A great deal of animal research implicates the serotonergic system in the control of anxiety and aggression (Olivier et al., 1991). Evidence supporting the modulatory role of 5-HT over anxiety and aggression has been obtained in animals selected for reduced aggression and tameness. Wild Norway rats that had been selected for reduced aggressiveness toward humans exhibit significant alterations involving 5-HT activity. The tame rats exhibit significantly higher levels of 5-HT and 5-hydroxyindoleacetic acid (5-HIAA) in the hypothalamus, as well as a 25% increase in tryptophan-hydroxylase activity in comparison to fearfully reactive and aggressive rats (Popova et al., 1990). The behavioral reactivity of genetically tame and aggressive rats was shown to differ significantly in response to stressful handling and aversive stimulation (Nikulina et al., 1992). When pushed with a gloved hand, aggressive rats frequently attacked the glove, whereas tame rats showed no defensive reaction. When exposed to shock, tame rats launched fewer attacks toward one another than did aggressive counterparts. Predatory attacks directed toward mice were not differentiated between tame and aggressive rats: both groups killed mice within 1 to 3 minutes. Selection for tameness in silver foxes has resulted in similar modifications of the serotonergic system (Popova et al., 1991). Tame foxes show increased 5-HT levels in the midbrain and hypothalamus and higher levels of 5-HIAA in the midbrain, hypothalamus, and hippocampus. Tame foxes also exhibit a significant increase in tryptophan-hydroxylase activity in comparison to captive and aggressive foxes. Tame foxes produce 34% more tryptophan hydroxylase than do aggressive counterparts.

Dogs exhibiting impulsive CDA have been found to exhibit evidence of reduced 5-HT activity (Reisner et al., 1996). The cerebrospinal fluid (CSF) of aggressive dogs contains lower levels of 5-HIAA than that of nonaggressive controls (aggressive dogs, 202.0 pmol/ml, versus nonaggressive controls, 298.0 pmol/ml). 5-HIAA is a product produced by the breakdown of serotonin, with decreased CSF levels indicating reduced serotonin activity. A further reduction in CSF 5-HIAA levels was found in dogs that did not give a warning before biting (aggressive dogs not giving a warning, 196.0 pmol/ml, versus dogs that gave a warning, 244.0 pmol/ml). Low levels of CSF 5-HIAA have also been repeatedly found in people prone to exhibit impulsive aggression and violence. Mehlman and colleagues (1994) found that the severity of aggression exhibited by rhesus macaques was inversely correlated with CSF 5-HIAA levels, with monkeys having low levels of CSF 5-HIAA being more likely to exhibit severe aggression and other signs of decreased impulse control. Similar findings have been reported in the case of vervet monkeys in which decreased 5-HT levels are associated with increased irritability and aggression, irrespective of the monkey's status (McGuire and Raleigh, 1987).

Low levels of CSF 5-HIAA suggest the presence of some degree of dysfunction in the serotonergic system, perhaps involving the stress-related depletion of 5-HT, a chronic failure of affected dogs to produce adequate amounts of it, or other influences reducing its use and metabolism in the brain. In addition to serving a negative-feedback function restraining CRF output, circulating glucocorticoids appear to prime the impulse-controlling effects of 5-HT over cortical and thalamic sensory inputs via GABAergic (gamma-aminobutyric acid) interneurons (Stutzmann et al., 1998) (see *Startle and Fear Circuits* in Chapter 3). Hypothetically, in dogs where low cortisol levels present together with reduced 5-HT activity, one would expect to find an increased propensity to show impulsive aggression and other signs of emotional disturbance. Much of the current research seems to support the idea that 5-HT plays a significant role in the modulation of aversive arousal via GABAergic interneurons at the level of the amygdala—the emotional interpretive center of the anger-rage circuit:

> Decreased serotonergic functioning might result in deficient GABAergic modulation of excitatory sensory efferents, perhaps allowing innocuous sensory signals to be processed through the LA [lateral amygdala] as emotionally stimulating events. Overall, the net effect of 5-HT acting through GABAergic mechanisms in the LA appears to be inhibitory and may therefore serve as a modulator of affective sensory processing. (Stutzmann et al., 1998:3-4)

A variety of 5-HT-receptor subtypes have been identified, with at least 15 different ones currently known (Roth et al., 2000). The HT_{1B} receptor appears to mediate an inhibitory effect over aggression, whereas the 5-HT_{1A} receptor appears to mediate an antianxiety effect, at least in the case of mice and rats. The expression of these serotonergic receptors is dependent on a transcriptional factor, Pet-1 ETS, which is expressed in the embryo just before the first 5-HT neurons appear in the hindbrain. Mice lacking the ability to express Pet-1 do not develop normal 5-HT neurons. Interestingly, though, despite the absence of an effective serotonergic system, Pet-1 null mice show a surprising lack of abnormal structural or behavioral effects, other than becoming more aggressive and anxious as adults. Pet-1 nulls not only attacked more often than controls, they delivered significantly more bite wounds, suggesting a loss of bite inhibition. Consistent with these findings, Reisner and colleagues (1996) reported that, among dogs diagnosed with dominance aggression, those dogs delivering hard and injurious bites tended to have lower levels of CSF 5-HIAA and CSF homovanillic acid (HVA), a dopamine metabolite. Although 5-HT neurons generally exert an inhibitory influence, 5-HT_2 neurons appear to be an exception to this rule. For example, 5-HT_2-receptor agonists appear to facilitate the expression of defensive rage in cats (see Gregg and Siegel, 2001). Interestingly, in this regard, Sugrue (1983) has noted that one of the effects of antidepressants is gradually to downregulate the 5-HT_2 receptor. Recent neuroimaging studies of nonaggressive and aggressive dogs performed by Peremans and colleagues appear to support the hypothesis

that impulsive CDA may be linked to an aberrant upregulation of the 5-HT_{2A} receptor in the frontal cortex (see *Stress, 5-HT_{2A} Receptor Upregulation, and Aggression* in Chapter 10).

Serotonin and Dominance

Raleigh and colleagues at UCLA (1991) performed a valuable study that appears to significantly question the role of aggression in the acquisition of social dominance, at least in the case of vervet monkeys. Vervet monkeys were observed interacting in 12 socially organized troops consisting of three adult males, three or more females, and a variable number of young. In each troop, one male had assumed a dominant rank. The alpha male was removed from the troop, and the remaining monkeys were differentially treated, one receiving a 5-HT agonist or antagonist and the other given a placebo. Two treatment programs were implemented: one to increase 5-HT activity with fluoxetine or tryptophan, and the other to decrease it with 5-HT antagonists. During the various treatment phases, the pair was observed for changes in social behavior and rank. The experiment consisted of several phases and a treatment reversal in which monkeys receiving the agonist were given the antagonist and vice versa. The results showed that monkeys treated with fluoxetine or tryptophan consistently became dominant over cagemates given a placebo. Conversely, monkeys treated with a serotonin depleter (fenfluramine) or antagonist (cyproheptadine) consistently became subordinate to placebo-treated controls. The monkeys treated with fluoxetine or tryptophan consistently achieved a dominant status, even though they became less overtly aggressive, more friendly, and less active as the result of the treatment protocol. On the other hand, the monkeys treated with the antagonists were markedly more aggressive, less sociable, more active, and consistently became subordinate to placebo-treated cagemates. The monkeys treated with fluoxetine or tryptophan appeared to become socially dominant because of an improved ability to interact with other monkeys; that is, they became more socially competent. In an earlier study, Raleigh and coworkers (1985) found that the affiliation-enhancing effects of fluoxetine and tryptophan were facilitated by the social status of the monkeys treated. Dominant males were much more responsive to treatment with fluoxetine and tryptophan than were subordinate males. The researchers conclude that a high degree of independence exists between dominance and aggressiveness, with competent social interactions appearing to mediate social dominance.

Similar findings have been reported by Fonberg (1988). She found that previously submissive cats became dominant under the influence of chronic treatment with imipramine. The medication did not appear to have an effect on social dominance by raising aggression levels, but by some other mechanism, perhaps associated with an increase in predatory motivation and enhancement of the hedonic reward:

> Direct correlations between the gaining of dominance status and aggressive display were not found. Cats that became submissive as the result of DMA damage [dorsomedial amygdala lesions] regained their dominance under imipramine. It was suggested that imipramine enhanced dominance rather by increasing predatory motivation, and hedonic aspect of reward, than by raising the level of aggression. Some kind of "confidence" in the efficacy of action may also play an important role. The beneficial effect of imipramine in the treatment of depressive patients may reflect a similar mechanism. The increase of predatory behavior in normal or LH [lateral hypothalamus lesions] nonkillers under imipramine may also support the assumption that imipramine enhances predatory motivation. (208)

Not only is aggression not always necessary to establish and maintain dominance status, dominance maintained without aggression may result in more stable social relations. Fonberg concludes,

> The only conclusion which I can suggest is that aggression is not an indispensable factor for gaining and sustaining dominance, and that some unknown "dominance factor" is also a very important both for human subjects and other animals. (211)

Dominant dogs appear to be possessed by a dominant attitude and social competence, whereas aggressive dogs frequently lack confi-

dence, appear to be socially incompetent, and bite reactively under the disorganizing influence of confusion, irritability, frustration, or anger (see *Dominance: Status or Control* in Volume 2, Chapter 8). Fuller (1973) has reported that puppies exposed to early isolation suffer disturbances of attention, increased reactivity, and reduced abilities to habituate to environmental stimulation. He observed that isolated puppies were consistently dominated by better-socialized counterparts. Dominance is far more a matter of attitude than physical attributes, as stressed by Trumler (1973):

> Mental rather than physical superiority, whether in another of his kind or in man, is far more impressive to a dog. Between dogs which know each other well physical strength is always being measured, whereas authority remains unquestioned. (198)

Arginine Vasopressin, Testosterone, and Serotonin

In dogs, arousal and de-arousal patterns may be significantly different in the cases of predatory behavior, dominance aggression, and affective attacks motivated by anger and rage. In addition to relatively discrete circuits dedicated to quiet and affective attack, conspecific aggression exhibited during dominance contests between males appears to be mediated by a dedicated circuit, perhaps involving the combined influences of AVP and testosterone under the modulatory influence of 5-HT (Ferris et al., 1997). Whereas affective attack is strongly associated with anger and rage, dominance aggression between males competing for status and breeding rights does not appear to rely on anger and rage for its expression (Panksepp, 1998).

Various lines of research suggest a prominent role of AVP in the development of conspecific intermale agonistic behavior (see *Arginine Vasopressin and Aggression* in Volume 1, Chapter 3). The aggression-facilitating effect of AVP appears to depend on the presence of testosterone and testosterone metabolites (e.g., estradiol and dihydrotestosterone). Both vasopressin and testosterone are perinatally active, suggesting that they interact early in an animal's development and set the stage for dimorphic sexual and behavioral differentiation. The basic organismic plan of mammals is based on female characteristics, with the appearance of maleness depending on the influence of testosterone at various points in the development of an animal's ontogeny. In dogs, just before and after birth, the testes produce a surge of testosterone that exerts a pronounced differentiating influence on neural tissue via the aromatization of testosterone into estradiol by brain aromatase (Kelly, 1991). Estrogen-sensitive neurons are widely distributed in the brain, including limbic and cortical areas, exerting pervasive nonreproductive dimorphic influences on behavior. The perinatal influence of testosterone on neural organization becomes most evident at puberty, when another surge of testosterone occurs in the dogs at 6 to 8 months (Hart, 1985) and the emergence of dimorphic behavior associated with maleness, notably increased scent-marking behavior and intermale aggression, and secondary male characteristics begin to emerge. Under the influence of maternal stress, fetal changes associated with androgenization may be significantly disturbed (Panksepp, 1998), perhaps explaining somewhat the variable expression of male-characteristic behavior in adult dogs.

Testosterone and its metabolites interact with various neuropeptides. Most important, though, in terms of the expression of male-characteristic behaviors is its interaction with AVP. Along with CRF and the closely related peptide oxytocin, AVP is produced in the paraventricular nucleus of the hypothalamus. Oxytocin and AVP are also released into the bloodstream via the pituitary gland. AVP is also synthesized by neurons in the medial amygdala and the BNST. AVP production is sexually dimorphic, with males producing more AVP than females and expressing a greater number of androgen receptors in the medial amygdala (Cooke et al., 1998). Recall that the medial amygdala and BNST are closely involved in mediation of affective aggression, with the medial amygdala playing a central role in the rapid emotional interpretation of potentially dangerous situations. Males appear to be more risk prone, perhaps reflecting changes in the medial amygdala and other related neural areas influenced by the interaction of testosterone and AVP. The distribution of AVP receptors in the brain varies significantly from species to species,

which suggests that the neuropeptide plays a significant role in the differentiation of species-typical social behavior (Young, 1999).

In golden hamsters, AVP facilitates scent marking and offensive aggression, an effect that is dependent on the presence of testosterone in the ventrolateral hypothalamus (Delville et al., 1996). Earlier studies found that AVP mediates scent-marking behavior (flank marking) in hamsters when it is injected into the anterior hypothalamus. This behavior appears to be influenced significantly by social dominance, with dominant animals marking more frequently than subordinates. However, when subordinate hamsters are stimulated to exhibit more scent-marking behavior, the increased marking in the presence of a more dominant conspecific does not evoke offensive attacks or an increase in marking by the dominant animal (Ferris and Delville, 1994). Aggression can also be evoked by AVP in the anterior hypothalamus, an area enervated with a high concentration of 5-HT terminals and 5-HT_{1B}-binding sites interacting with AVP-responsive neurons. 5-HT is believed to perform an inhibitory role over offensive aggression and scent marking. Ferris and colleagues (1997) found that enhancement of serotonin activity with fluoxetine exerted a significant inhibitory effect on offensive aggression in experienced fighters. In addition, fluoxetine exerted a strong inhibitory influence over AVP-induced aggression directed against conspecific intruders. In the hamsters treated with fluoxetine, scent-marking behavior was completely suppressed.

Early stress may dramatically affect the activity of AVP and CRF. As previously noted, both AVP and CRF are produced in the same area of the hypothalamus and appear to interact at various levels of neural organization. As the result of postnatal stress, excessive AVP/CRF activity via the proliferation of AVP and CRF receptors in areas of the brain involved in the expression of affective aggression (e.g., medial amygdala, BNST, and PAG) may dispose some dogs show lower aggression thresholds. Stress associated with maternal separation has been shown to exert profound and lasting effects on the proliferation and density of CRF-binding sites, HPA dysregulation, and various functional disturbances of interacting neurotransmitter systems (see *Maternal Separation and Stress* in Chapter 4). In dogs, decreased glucocorticoid levels result in an increased release of peripheral AVP, with cortisol infusions producing a significant reduction of plasma AVP (Papanek and Raff, 1994). Cortisol may also restrain central AVP activity via negative feedback, a function that could be significant in dogs exhibiting aggression in association with low cortisol levels. Further, a cortisol-mediated reduction of AVP, the anti-diuretic hormone, may help to explain the loss of bladder control among many separation-reactive dogs and dogs experiencing stressful social and environmental transitions.

Immune Stress and Cytokines

Adverse emotional and mental states have been implicated in a variety of somatic disorders (McMillan, 1999), including gastric dilatation-volvulus in dogs—a condition that large, depressed, and fearful dogs appear to be at increased risk of developing (Glickman et al., 2000). Health and disease may also exert adverse effects on behavior. Serpell and Jagoe (1995) have reported the existence of a significant correlation between sickness in puppyhood and the subsequent development of behavior problems, including owner-directed and stranger-directed aggression, increased social fearfulness and reactivity, separation-related barking, and excessive mounting behavior by male dogs. A similar association between sickness in puppyhood and adult aggressiveness was detected among English cocker spaniels (Podberscek and Serpell, 1997). In both studies, the authors attribute the increased incidence of behavior problems associated with early sickness to various socialization deficits or excesses accruing as the result of the way sick puppies are treated by their owners (e.g., increased attention, care, and indulgence). However, another interpretation is also possible. Perhaps the positive correlation between early disease and an increased risk of behavior problems stems from the same root causes; that is, pediatric disease and adult behavior problems may be the short-term and long-term effects of early ontogenetic stressors. Murphree (1973) reported that nervous pointer dogs were

prone to develop mange between months 3 and 9, suggesting the possible involvement of stress-related immunosuppression (see *Nervous Pointers* in Volume 1, Chapter 5). Recently, Guy and colleagues (2001) have reported that dogs treated for pruritic skin disorders are at twice the risk of biting someone than are counterparts not exhibiting such problems.

Ongoing psychoneuroimmunological research indicates that a system of bidirectional communication exists between the brain and the immune system. Numerous classical conditioning experiments have demonstrated that the central nervous system exerts a conditioned modulatory influence over immune activity (Ader and Cohen, 1985). The immune system appears to interact closely with the FFS, perhaps as the result of an evolutionary process in which the stress system has co-opted by immune mechanisms that are conducive to supporting rapid preparation for emergency action (e.g., HPA activation) and promoting recuperation or reducing risk of infection from injuries incurred from fighting or other dangerous activities (Maier and Watkins, 1998). As the result of injury or invasion by a foreign substance, immune cells are activated. Immune cells perform a variety of complementary functions, requiring communication between cells and the rest of the body. This communication function is performed by a variety of substances called *cytokines*. Cytokines mediate immune responses to bacteria, viruses, and foreign proteins. Animals exhibit both specific and nonspecific immune responses. Specific immune responses take time to develop, but eventually provide the organism with lasting protection against the target antigen by producing antibodies. In contrast, nonspecific immune responses occur much more rapidly (within 1 to 2 hours). One type of nonspecific immune response involves the activation of a class of phagocytes known as *macrophages*. Activated macrophages perform many functions, including the synthesis and release of proinflammatory cytokines (e.g., interleukin 1, interleukin 6, and tumor-necrosis factor). In addition to facilitating a local inflammatory reaction, cytokines produce far-reaching changes throughout the body and brain. Within the brain, cytokines appear to increase NE and 5-HT turnover significantly—effects comparable to those produced by environmental stress (Dunn et al. 1999). These neural changes result in numerous affective, behavioral, and cognitive symptoms associated with sickness (e.g., fever, chills, reduced activity, increased sensitivity to pain, depression, and increased HPA-axis activity).

Since cytokines cannot freely pass through the blood-brain barrier, cytokine-mediated neural changes probably occur via another pathway, perhaps an active transport mechanism dedicated to specific cytokines. The exact route or routes of communication between cytokines and the brain is controversial (Blatteis and Li, 2000), but at least some communication between peripheral cytokines and the brain is mediated via afferent vagus-nerve transmissions (Romanovsky et al., 1997)—a pathway that may have been co-opted by epinephrine (adrenaline) to mediate the central changes associated with flight-fight activation. Whereas afferent vagal signals may activate central responses to immune stress, efferent vagal signals appear to modulate the effects of immune stress on the body (Borovikova et al., 2000), mirroring the opponent parasympathetic effects (decreased heart rate and so forth) that the vagus nerve exerts over sympathetic arousal and the FFS. According to this hypothesis, cytokines trigger afferent vagal signals that are carried to the brainstem (medulla) and relayed to various parts of the brain (e.g., hypothalamus and hippocampus), where they stimulate the synthesis and release of central cytokines. These substances, in turn, trigger a cascade of cytokine-dependent neural events that collectively produce the symptoms of sickness and distress. Studies examining the sensitization effects of cytokines on central monoamine neurotransmitter systems have shown that 5-HT activity in the central amygdala undergoes significant sensitization following exposure to immune stress, as does dopamine activity in the prefrontal cortex. Animals exposed to cytokine activation also show a marked increase in HPA-axis responsiveness to subsequent immune stress (Hayley et al., 2001). The sensitization mediated by immune stress, affecting neurotransmitter activity in brain areas associated with executive control, fear, and aggression, suggests that sickness and

disease might produce a lasting dysregulatory effect in some predisposed dogs, even after the sickness has completely passed. Further, perhaps chronic subclinical infections (e.g., Lyme disease) resulting in persistent immune stress and cytokine activation may alter behavioral thresholds controlling flight-fight reactions and adversely affect a dog's ability to cope with environmental stressors. Although nothing very persuasive has been published on the subject, adverse psychiatric symptoms of Lyme disease have been anecdotally reported in human patients (Fallon et al., 1993).

The possibility that immune stress in association with disease may produce lasting epigenetic changes in the dog's behavior offers an alternative explanation for Jagoe and Serpell's findings (Dreschel, 2002). Human psychiatric research indicates that some forms of rapid-onset obsessive-compulsive disorder in children may be related to a history of streptococcal infection (Swedo et al., 1998). In addition to obsessive-compulsive disorder and tic disorder, affected children often exhibit a variety of comorbid symptoms, including emotional and cognitive deficits, separation anxiety, hyperactivity, and increased oppositional behavior. Granger and associates (2001) have reported that stressing the immune system of neonatal mice causes them to become more socially reactive and fearful as adults. Conceivably, and this is a speculative leap, some predisposed dogs may be adversely affected by the immune stress associated with vaccinations—a hypothesis that deserves clinical and experimental attention (Dreschel, 2002). In the case of human patients, immune stress resulting from vaccination with live attenuated rubella virus has been shown to induce depressive symptoms in socially vulnerable teenage girls for up to 10 weeks following vaccination (Yirmiya et al., 2000). Since the neural response to immune stress is markedly sensitized by repeat exposure at a 1-day interval and not after a 28-day interval (Hayley et al., 2001), vaccinations given on a frequent schedule may be more prone to produce adverse cumulative effects than are vaccinations spread out over time. Even when dogs are vaccinated once a year, however, they show increased levels of fecal cortisol metabolites (417% above baseline levels) 1 to 2 days following injections (Palme et al., 2001), indicating an association of the procedure with stress-related activation of the HPA system. Finally, extrapolating from these investigations, one might reasonably assume that dogs and puppies may be more reactive to environmental and behavioral stressors for 24 to 48 hours following vaccination. Adverse behavioral effects following vaccination may be more likely in the case of dogs and puppies exhibiting unstable and reactive temperaments, especially when under the influence of heightened behavioral stress prior to vaccinations. The relationship between early stress, disease, immune-system activation, vaccinations, and behavior problems is an important area for future basic and epidemiological research.

Pharmacological Control of Aggression

Serotonergic medications are frequently prescribed to treat aggression problems in dogs, but the efficacy of such drugs to moderate or inhibit canine aggression remains controversial, with most studies to date indicating that tricyclic antidepressants (TCAs) perform on par with placebo. In addition, no compelling evidence currently exists showing that SSRIs perform any better. The TCAs most commonly prescribed to ameliorate behavior problems are amitriptyline and clomipramine. Amitriptyline appears to block the presynaptic reuptake of 5-HT and to an even greater extent the reuptake of NE, but its therapeutic effect appears to follow primarily from the sensitization of postsynaptic neurons. Clomipramine, on the other hand, is much more specific with regards to the inhibitory effect it exerts on serotonin reuptake. Whereas amitriptyline produces a twofold greater effect on NE reuptake than it does on 5-HT reuptake, clomipramine produces a fivefold greater effect on 5-HT reuptake than on NE reuptake, exceeding the potency of fluoxetine as a serotonergic agent by over twofold (Julien, 1995). Clomipramine appears to inhibit the reuptake of serotonin by means similar to that of SSRIs. As a result of elevated 5-HT activity associated with treatment, 5-HT$_{1A}$ autoreceptors located on the 5-HT neuron are gradually desensitized, thereby causing it to release

more 5-HT at the presynaptic terminal. Clomipramine, like other TCA drugs, may produce some typical side effects (e.g., mild sedation) and anticholinergic effects (e.g., dry mouth, urinary retention, and constipation), but to a lesser extent than amitriptyline, which can produce a potent histamine-related sedation effect (Julien, 1995). Despite an evident effect on 5-HT activity, neither clomipramine (White et al., 1999) nor amitriptyline (Virga et al., 2001) have been proven to be of clinical value for the treatment of owner-directed aggression. This is the conclusion of two double-blind and placebo-controlled trials performed to evaluate the efficacy of these commonly prescribed drugs. Neither study showed any significant benefit attributable to either medication; that is, dogs exhibited nearly the same behavioral course of change whether they were given the placebo or the TCA.

Perhaps the most commonly prescribed SSRI for the control of aggression in dogs is fluoxetine. The potential benefits of fluoxetine probably stem from a two-prong effect it appears to exert on 5-HT activity: decreased anxiety and lowered aggression thresholds (Olivier et al., 1991). Although probably effective in the case of aggression associated with impaired 5-HT function, no controlled study to date has shown that fluoxetine works any better than clomipramine for the control of owner-directed aggression or intermale aggression in dogs. Only one clinical trial to date has been performed to evaluate the effectiveness of fluoxetine for the control of dominance aggression (Dodman et al., 1996), but the quality of the study has been seriously questioned (White et al., 1999). The study involved nine dogs that were selected based on a history of owner-directed aggression. All of the dogs were given a placebo 1 week before commencing a 4-week course of treatment with fluoxetine. A significant reduction in aggression was found in all of the dogs after the treatment program was completed. Despite these promising results, the researchers failed to achieve their stated objective: "to determine the efficacy of fluoxetine in the treatment of owner-directed canine dominance aggression by means of a placebo-controlled blind study" (Dodman et al., 1996:1585). In fact, the study was neither blind nor placebo controlled, but rather an "incomplete-crossover design" (Simpson and Simpson, 1996:106), throwing into doubt the value of the results reported (White et al., 1999). Given the lack of efficacy shown by TCAs and the absence of more compelling evidence regarding the value of SSRIs, as things currently stand, the use of serotonergic drugs have not been definitively shown to be an effective treatment for household aggression problems.

TCAs and SSRIs may be more effective in cases where a significant disturbance of 5-HT or NE activity is indicated by the presence of high levels of anxiety and excitability, panic, and impulsiveness (Landsberg, 2001). When TCAs are given to normal humans, their mood is not enhanced by the medication; it is only in the presence of neural disturbances affecting 5-HT and NE functions that a benefit is obtained by their use. Although a previous study showed a strong relationship between decreased levels of CSF serotonin and dopamine metabolites and dominance aggression (Reisner et al., 1996), this potential endophenotype (i.e., a quantifiable physiological marker predicting risk or presence of disorder) predicting dominance aggression has turned out to be of limited clinical usefulness. Mertens and colleagues (2000) failed to find any significant differences in the plasma or CSF 5-HIAA or 5-HT concentrations of dogs presenting with dominance aggression (N = 9) and a control group of nonaggressors (N = 20), concluding that such markers are of little value for confirming the diagnosis of dominance aggression. Nevertheless, given the earlier work of Reisner and colleagues, such laboratory tests may still be of value for helping to detect the subgroup of dogs that might exhibit a deficiency of 5-HT activity and are most likely to respond beneficially to serotonergic agents. In their study, springer spaniels were disproportionately represented in the experimental group, suggesting the possibility that aggression problems exhibited by this breed may show an increased responsiveness to serotonergic medications.

SSRIs often take weeks to become fully effective, even though the presynaptic reuptake inhibition produced by such medications

(e.g., fluoxetine) appears to occur within minutes (Blier and De Montigny, 1994). The rapid increase of 5-HT occurring as the result of treatment with fluoxetine causes 5-HT_{1A} autoreceptors at the level of the midbrain raphe nuclei to slow down the release of serotonin at the terminal, where 5-HT_{1B} autoreceptors also exert an inhibitory effect on the release of serotonin. This braking effect is gradually reduced as 5-HT_{1A} autoreceptors are slowly desensitized, thereby attenuating their negative-feedback control over 5-HT release. To induce a more rapid onset of therapeutic effect, pindolol, a mixed ß-adrenoceptor/5-HT_{1A} antagonist has been used in combination with SSRIs to treat human depression. Reportedly, the combination both accelerates and enhances the effects of SSRIs. Pindolol may facilitate SSRI actions by partially inhibiting 5-HT_{1A} autoreceptors and other modes of action (Artigas et al., 2001), for example, central ß-adrenoceptor blockade (Cremers et al., 2001). Since pindolol exerts an inhibitory effect over 5-HT_{1A} receptors, it *may* elevate anxiety levels while exerting a more rapid onset of modulatory control over aggressive impulse.

Given the effectiveness of fluoxetine to modulate offensive aggression, scent marking, social dominance, and affiliative behavior in several animal species, perhaps 5-HT-enhancing drugs would be useful to control dog-dog aggression, especially aggression between dogs sharing the same home (Houpt, 2000). Also, fluoxetine or 5-HTP might offer significant benefit for the control of refractory canine urine marking, as Pryor and colleagues (2001) have convincingly shown in the case of fluoxetine for the control of feline urine-marking behavior. Both fluoxetine and 5-HTP have been shown to stimulate an increased production of glucocorticoids, an effect that may be beneficial in cases of aggression associated with low cortisol levels. Finally, a potent selective 5-HT-reuptake inhibitor that may have potential value for the treatment of stress-related behavior problems occurring in association with dysregulated 5-HT activity is paroxetine. Paroxetine may be particularly beneficial in the case of dogs exhibiting signs of chronic stress or abnormalities involving the HPA system (e.g., low cortisol). Reportedly, paroxetine exerts a pronounced effect on central CRF, helping to normalize the HPA axis and promoting a more adaptive response to stress (Ladd et al., 2000).

In accordance with the dead-dog rule (see *Dead-dog Rule* in Volume 2, Chapter 2), most treatable aggression problems are best approached by training owners and dogs how to get on together more competently and affectionately, rather than targeting aggression with physical punishment, mechanical restraint, or pharmacological suppression. Given that the mere absence of aggression is not a particularly reliable predictor of risk, emphasis is placed on mediating changes conducive to more competent, playful, relaxed, and friendly interaction between the owner and family members. Establishing a pattern of behavior, with or without the support of drugs, that is incompatible with aggression appears to provide a far better predictor of relative aggression risk, but nothing is fail-safe in such matters. Many drug-study protocols appear to be overly preoccupied with the suppressive effect of medication rather than focusing on the subtle nuances and changes occurring in the dog's emotional tone and emergent organizing processes that may, in fact, be facilitated by the medication but remain undetected by the assessment instrument used to monitor change. Medications such as SSRIs may steadily enhance a dog's ability to cope more adaptively with stressful situations and to interact more competently and affectionately with the owner. Many of the neurobiological effects of SSRIs, in particular, appear to be mostly subtle, working slowly and thereby integrating a complex attunement process involving a dauntingly complicated network of serotonergic processes and neural interactions. For the full benefits of such therapy to develop and mature, perhaps the medication needs to be maintained for much longer periods than typically found in current protocols. Drug trials lasting only a few weeks—that is, ending just at a point when the drug is becoming most potent and active—may not be provide enough time to reveal the full merit of SSRI therapy on dog aggression problems. Further, more sensitive and standardized assessment instruments may need to be developed for detecting and track-

ing gradual behavioral changes. Finally, it seems crucial that efforts be taken to develop sharper diagnostic inclusion criteria and endophenotypic markers for sorting out aggressive phenotypes in order to determine which ones might benefit most from SSRI therapy:

> It is possible that in dogs, aggression that is a typical, albeit problem, behavior will not be affected by serotonergic drugs, but abnormal aggressiveness, which develops less frequently in dogs, may be affected. (White et al., 1999:1290–1291)

Note: The foregoing information is provided for educational purposes only. If considering the use of medications to control or manage a behavior problem, the reader should consult with a veterinarian familiar with the use of drugs for such purposes to obtain diagnostic criteria, specific dosages, and medical advice concerning potential adverse side effects and interactions with other drugs.

PLACEBO EFFECTS, ENDOPHENOTYPES, AND THE DEAD-DOG RULE

White and colleagues' (1999) data revealed a robust placebo effect occurring precisely in the treatment time course when one might *expect* to observe maximum benefits resulting from treatment with clomipramine or SSRIs, a pattern consistent with the positive findings reported by Dodman and colleagues (1996). Interpersonal expectancy effects in the treatment of aggression problems can be extremely powerful and sometimes even welcome and beneficial, appearing to exert a constructive influence that a skillful behavior therapist can use to promote positive change. However, in the case of research, placebo effects make it impossible to interpret the significance of the data collected, essentially making the work useless or, at best, stimulating additional research with appropriate controls to limit placebo and experimenter-bias effects.

Most veterinary behavior data are collected secondhand via questionnaire instruments, filtered through the owners' perception of their dog's behavior and its response to treatment. In addition, the owner is typically asked to perform some set of procedures, not to interact with the dog in some specified ways, or not to change their behavior toward the dog in any way. In a sense the owner becomes a coexperimenter, often fully aware of what the experimenter is trying to achieve by way of the study. Naturally, the owner's involvement jeopardizes the objectivity of the study at various points. Many owners desperately want their dogs to improve and may do things unconsciously to facilitate that improvement or begin to see changes where none have actually occurred, thereby potentially skewing what they observe with an overly optimistic bias. As a result, three basic concerns are raised by such studies: (1) owner reports may lack objectivity, (2) owners may not follow instructions competently or compliantly, and (3) study results will tend to confirm the experimental hypothesis. Without the safeguards afforded by a randomized, double-blind, and placebo-controlled experimental design, findings derived from such investigations are extremely difficult to analyze and interpret, perhaps ending up being a waste of time and money. Even with the proper controls in place, problems might still stem from items 1 and 2. These almost insurmountable difficulties point to the need for objective physiological or neurobiological markers or endophenotypes correlated with serious behavior problems and their resolution. Studies evaluating PPI testing, heart-rate changes in response to petting and massage, stress-related heart-rate and blood-pressure divergence (*see Autonomic Arousal, Heart Rate, and Aggression*), oxytocin levels in response to social contact/petting, cortisol response to mild stressors, blood-pressure and vagus-nerve monitoring, and so forth may prove useful in this regard. For example, SSRIs appear to mobilize an oxytocinergic-antistress response (Uvnäs-Moberg et al., 1999), an effect that may alter a dog's PPI and cardiac response to touch, thereby potentially establishing an objective marker (endophenotype) for gauging the efficacy of such medications. A chronic effect of clomipramine is to downregulate kappa- and mu-opioid receptors, suggesting the possibility that one therapeutic effect of the medication is to reduce opioid-mediated inhibition of central oxytocin

(McDougle et al., 1999), an effect that should be reflected in changes of peripheral oxytocin levels (see Brown et al., 2001).

The stated goal of cynopraxic therapy and training is to promote interactive harmony and to enhance the human-dog bond, but how can one quantify such an objective? For practical purposes, success is quantified by informal and formal assessments and comparisons of pretraining and post-training expectancy divergence and convergence indicators (see *Puppy Profile Sheet* in Volume 1, Chapter 2). For example, during pretraining interviews, the owner may be instructed to list on one side of a sheet of paper all of the dog's minor and major adjustment problems and on the other side a collection of corresponding positive statements about what the owner would consider the best possible outcome of training efforts. The owner is then instructed to draw lines between the two sets of items, connecting related items and thereby establishing a series of expectancy continuums between the owner's ideal and the dog's actual behavior. These items can then become the topic of counseling to form realistic objectives and means to attain the owner's goals. A major advantage of this approach is that it establishes a personalized profile of the dog's specific adjustment difficulties from the owner's perspective and in terms relevant to the owner's goals. Not only do dogs exhibit significant variability, relationships between people and dogs are also affected by tremendous variation. What may be a problem for one person may be a source of joy for another. The profile helps to contextualize the dog's behavior within a relationship and a home, thereby enabling the cynopraxic therapist to provide counseling and rational training relevant to improving the human-dog bond while simultaneously working to enhance the dog's quality of life.

This procedure not only provides vital information about the adjustment problem, but allows the owner to think through carefully what he or she wants to achieve as the result of training and behavior therapy. The set of expectancy continuums given by the owner can be formalized and used to construct a worst-case and best-case grouping of related items with a 10-point scale between them, as used in the puppy profile questionnaire. With regard to experimental applications and data collection, the owner's items might be included in a standardized and validated owner-expectancy assessment developed for research purposes—something that remains to be done. At a glance, the owner can quickly note where the dog currently stands on the scaled continuum with an X and indicate what he or she would like to accomplish through training by placing an O over the appropriate point. The divergence between these two points on the scale is the expectancy-divergence score. Upon completion of the training and therapy program, a second owner-expectancy assessment is performed, and a training outcome score is assigned by comparing and recording differences between the pretraining scores and the post-training scores. By adding these scores together and then dividing the sum by the total number of items in the assessment, a social-conflict score is yielded. Success is measured in terms of a progressive trend toward a convergence between the owner's expectations and what the dog does, indicating a reduction of interactive conflict. In addition, quality-of-life improvements (e.g., time in crate, time on walks, time playing, and time training) are tracked by having the owner keep relevant records. This method of assessment is consistent with the dead-dog rule and seems to provide a valid measure of change relevant to the improvement of the human-dog bond.

PART 2: DEVELOPMENT AND CONTROL OF PUPPY COMPETITIVE BEHAVIOR

TEMPERAMENT AND AGGRESSION

Organized activity depends on the presence of an emotional balance produced by the complementary influences of inhibition and excitation. In addition to adverse developmental experiences, some dogs appear to be influenced by a genetic predisposition toward emotional instability and reactivity, corresponding to what Pavlov described as the choleric temperament (c type) (see *Experimental Neurosis* in Volume 1, Chapter 9).

Such dogs may be significantly more prone to exhibit behavioral disturbances associated with social environmental stressors (see *Temperament Testing* in Appendix D). These differences appear to express themselves at an early age in wolves (MacDonald, 1983) and dogs (Senay, 1966). Senay found that puppies prone to high levels of emotional arousal and reactivity were more avoidant and aggressive when approached than were puppies showing a more relaxed and organized response to human contact. These temperament differences were apparent at an early age and persisted throughout the first year, suggesting that they may due to inherited deviations affecting arousal levels and stimulus-reactivity thresholds. A proneness to excessive excitability and reactivity may cause dogs to engage in more disorganized and reactive behavior (withdrawal, avoidance, and aggression) when stimulated by social contact, whereas dogs functioning under the influence of moderate arousal and relaxation may be more prone to engage in organized behavior (approach, affiliation, and cooperation) under the influence of similar social stimulation. In addition to social avoidance and aggression, puppies exhibiting emotionally reactive behavior showed physiological signs of autonomic arousal (e.g., tachycardia and submissive urination). Puppies genetically prone to disturbances associated with excitability and reactivity excesses may also be more susceptible to the harmful influences of adverse rearing practices and biological stress.

TACTILE STIMULATION AND ADAPTATION

Tactile experiences and emotions share a number of common characteristics that suggest an ontogenetic link between taction and the development of emotional responsiveness and tone. Both touch and emotion are hedonically valenced and associated with varying degrees of subjective pleasure or pain; they both produce motivationally short-lived arousal prompting immediate behavioral adjustment (attraction or aversion) or more lasting and inescapable discomfort (e.g., throbbing pain or hurt feelings); they both function to direct dogs to attend to and respond to environmental stimulation selectively in order to perpetuate or terminate it; and they both can function as means to reinforce or suppress behavior.

Early tactile stimulation in the form of handling and gentling exerts profound and long-lasting influences on health (resistance to disease), activity levels, learning and problem-solving abilities, confidence, and emotional reactivity. Tactile stimulation is a significant source of potential reward for puppies and dogs (Fonberg et al., 1981), cats (Wenzel, 1959), and rats (Burgdorf and Panksepp, 2001). Rats seem to enjoy tactile stimulation as a prelude to play, with tickling of certain skin areas inducing ultrasonic chirping (Panksepp and Burgdorf, 2000). Among puppies, tactile stimulation associated with play enhances affection, social expressiveness, empathy, and restraint (bite inhibition). Just as tactile stimulation can produce disorganized and reactive behavior as the result of neurotogenic or traumatic experiences, therapeutic procedures using tactile stimulation appear to be highly effective in treating emotional disturbances originating in adverse somatosensory experiences (see *Posture-facilitated Relaxation Training* in Chapter 7).

Somatosensory systems promote attachment and social bonding via proximity seeking contact comfort and affect attunement. Puppies exhibit a strong preference for contact with soft objects, spending more time with cloth surrogate mothers versus time spent with wire surrogates providing milk (Igel and Calvin, 1960). Other studies have shown that contact with soft objects produces a significant reduction in separation distress in isolated puppies (Pettijohn et al., 1977). Petting has been shown to modulate adverse emotional reactions (Gantt, 1944; Fuller, 1967), restrain HPA-system activity (Hennessy et al., 1998), and decrease physiological arousal associated with aversive stimulation (Lynch and McCarthy, 1967 and 1969). Tactile stimulation mediates a potent effect on emotional learning and reactive thresholds via the autonomic nervous system and endocrine activity. The emotions associated with touch selectively activate and organize a puppy's behavioral output in the opposing directions of approach or withdraw in response to social

and environmental sources of tactile stimulation. Tactile-related emotions exert a pervasive influence on social behavior and development. Close social contact and tactile stimulation produce conditioned and unconditioned effects on attractive (e.g., affection) and aversive (anxiety, fear, irritability, and anger) arousal thresholds, mediating the expression of both organized and reactive behavior. Gantt (1971) observed that close contact and tactile stimulation produce three general patterns of arousal in dogs, depending on temperament and past experience: calming, agitation, and autistic (little or no response as observed in many genetically nervous pointer dogs). These differences in responsiveness are reflected in overt behavior, canine cardiovascular activity (e.g., heart rate and blood pressure), respiration rate, and endocrine activity.

As a result of the close and active social interaction with the mother and littermates, puppies may acquire somatosensory set points for a certain type and quantity of tactile stimulation not provided in the new home. Failure to obtain sufficient tactile or locomotor stimulation may represent a significant source of stress for newly adopted puppies, perhaps inducing a variety of compensatory behavioral changes, including hyperactivity, excessive contact-seeking and proximity-seeking behavior, overexcitability, and increased aggressiveness associated with frustration and irritability. Slabbert and Rasa (1993) have reported that German shepherd puppies removed from their mothers at week 6 failed to thrive and showed a significantly greater risk for disease and mortality than did puppies naturally weaned by their mothers between weeks 7 and 8. They also exhibited significant behavioral deficits: "Puppies weaned before 7 weeks of age are noisy and nervous. These seem to become fixed characteristics of the dog for life" (5). Puppies allowed to stay with their mothers through week 12 were healthier, gained more weight, and appeared better adapted. The cause of these disturbances in early-weaned puppies may be related to the premature loss of tactile stimulation and comfort contact.

Early adverse stress may exert immunological effects (e.g., immunosuppression) that could compromise a puppy's ability to fight infection. Although it is difficult to estimate the effect of postnatal stress on puppy development and the etiology of behavior problems, perhaps some important clues may be obtained by the confluence of early disease conditions, immune stress, and the incidence of adult behavior problems (see *Immune Stress and Cytokines*).

Play, Discipline, and Dominance

Dog owners typically establish dominance by asserting authority and setting behavioral limits on their puppies' activities. When confronted assertively, most puppies acknowledge the owner's authority and submit to owner directives. Although puppies are capable of learning at an early age, mature impulse-control abilities probably do not fully develop until dogs are 8 to 10 months of age. The most prominent ways in which owners respond to inappropriate behavior is by physical assertion (dominance) or by encouraging cooperation (leadership). Whether an assertion of physical force or encouragement is used largely depends on the owner's perception of the problem and the sort of motivations attributed to it. Ben-Michael and colleagues (2000b) found that assertions of force were most likely to occur in situations where the dog was perceived as being disobedient or out of control, both of which frequently evoked anger and irritability in owners. Encouragement and comforting strategies were most common in the case of fearful and submissive dogs and were motivated by feelings of compassion and anxiety. Some owners, however, may perceive fear-related behavior as personally aversive or offensive (e.g., a submissive dog urinates), thereby intensifying feelings of anger and irritability and reducing the likelihood of comforting activities toward the dog. The most common techniques used by dog owners to handle problematic behavior were mostly punitive (e.g., demand obedience, yell at the dog, or distract it). Comforting and encouraging the dog or ignoring the problematic behavior was less common. The least commonly used strategy was reward—findings that appear sharply at odds with the data and

assumptions elaborated by Hiby and colleagues (see *Owner Control Styles and Welfare Agendas* in Chapter 10). Physical punishment was mostly used in the case of aversive behavior (e.g., chewing on personal belongings or jumping on a bed) or disobedience. Punishment was avoided in situations where the dog was overexcited or fearful, in which cases owners were more likely to use distraction techniques (Ben-Michael et al., 2000a).

A significantly different picture of training and disciplinary activities has been presented by Koda (2001b) with regard to the ways in which guide-dog puppy raisers cope with inappropriate behavior. A series of direct observations of puppy raisers indicated that they rarely hit puppies and relied primarily on diversionary activities (e.g., play) or rejecting behavior (e.g., brief withdrawal of contact from the puppies) to control social excesses (e.g., mouthing). During observation periods, rejecting and, to a lesser extent, ignoring were considered to be effective in controlling biting, whereas distraction, talking to the puppy, initiating play, restraint, and showing objects to the puppy were all ineffective. These findings are difficult to interpret because of the way in which the observations were made. The presence of the observer, together with specific instructions from the guide-dog association not to use physical punishment, may have caused the puppy raisers to behave differently during observation periods than at other times when alone with the puppy. Koda has noted, however, that Japanese mothers typically avoid making their children behave by asserting authority, as "compared with American mothers" (86) (and apparently Dutch ones, too), suggesting the possibility that, in fact, the puppy raisers did avoid the use of physical punishment. Of particular interest was the finding that puppies may have exhibited an ontogenetic decline in biting and destructive activity as they matured, showing increased gentleness and willingness to cooperate. These maturational aspects of social interaction are particularly evident in the development of play behavior. Koda (2001a) found that, as puppies grew older, they tended to engage in play activities that evidenced improved impulse-control abilities. Unfortunately, it is impossible to determine whether these enhanced abilities for cooperative play are the result of ontogenetic changes or the result of puppy-raiser training activities occurring between observation periods.

Establishing dominance by setting limits on a puppy's behavior is typically accomplished by the application of varying amounts of punishment, a method of social control that is widely practiced by animals (Clutton-Brock and Parker, 1995) and the most common strategy used by people to control dog behavior (Ben-Michael et al., 2000a). Although assertive disciplinary interaction may be necessary and helpful to prevent problems (Hart and Hart, 1997), excessively harsh or frequent punishment is inappropriate and should be avoided. In response to such treatment, puppies typically show varying degrees of fear and submission, but some may be stimulated by frustration or anger and fight back. Defining and enforcing social rules for a puppy is critical for the development of appropriate adult social behavior, but excessive punitive interaction may cause the puppy to become progressively insecure and dependent on the owner or more reactive and aggressive. The risk of forming insecure attachments and excessive reactive coping styles is especially likely in situations where punishment is also associated with high levels of indulgent pampering, something that often follows severe punishment as the owner is moved by pangs of compunction and sympathy for the emotionally injured puppy.

Given the puppy's immature abilities with respect to exercising impulse control, punishment is unlikely to control social excesses effectively. As a result of limited success and growing frustration and irritability, owners and trainers may be tempted to escalate punitive efforts beyond what is appropriate and beneficial. Assertions of control using restraint, response prevention, abrupt stimulus change, assertive blocking, and loss of social contact may be effective, but physical punishment (e.g., hitting) should be avoided. Most importantly, in addition to defining what a puppy must not do, it is imperative to guide the puppy toward the expression of behaviors that it can do. Ideally, inhibitory training should be minimized. The puppy trainer should follow a philosophy of maximum overt differentiation (MOD) and systematic canalization of behavior into more

socially acceptable variations through structured play activities. Gradually, behavior-selection pressures involving contingent reinforcement and punitive actions can be used to shape a more precise and predictable behavioral repertoire. Young puppies are particularly receptive to incentive-based training, especially activities that involve play, small treats, and affectionate encouragement. Play provides an ideal means for controlling social excesses and inappropriate behavior by guiding puppies into alternative activities (canalization) to obtain gratification for otherwise socially unacceptable behavior (e.g., biting and jumping up). Play training promotes cooperative interaction based on a leader-follower bond, mutual appreciation, and heightened interactive joy. Disruptive, aggressive, or impulsive behavior is best controlled through the differential reinforcement of incompatible behaviors, response prevention, restraint, and brief TO. In addition to play, affectionate petting, vocal encouragement, and food rewards given in exchange for the performance of basic exercises (e.g., sit, down, stand, come, and stay) help puppies to learn how to communicate and cooperate with people. Integrated compliance training (ICT), whereby training is integrated into everyday household activities, helps to structure a puppy's behavior in accordance with general rules and expectations.

Precocious Aggression Problems

Although severe aggression problems are seldom seen in puppies, occasionally puppies do exhibit serious problems requiring behavioral intervention (see *Social Competition, Development, and Aggression* in Volume 2, Chapter 8). A common form of pediatric aggression involves possessive guarding of objects or food—a significant concern for families with children. Overly possessive puppies may guard food or other prized objects and threaten to bite if they are approached at such times. Training puppies to drop ("Drop it"), back away ("Leave it"), and resume possession ("Take it") of highly attractive toys and chew items is among the most important early lessons for such puppies to learn. Possessive-aggressive behavior in puppies may be indicative of a temporary developmental impulse-control deficit and may not necessarily predict adult possessive-aggression problems. Many puppies exhibiting possessive aggression appear to grow out of it (Marder, personal communication, 2000), but many also continue to exhibit the behavior as adults. Dunbar (1978) reported that adult male beagles rarely attempt to take bones away from young puppies, but always take them away from 7-month-old ones. This observation may be related to the ontogenetic emergence of improved impulse-control abilities in adolescent dogs. Adult dogs may recognize that puppies simply cannot control the impulse to protect such possessions.

As the result of biogenetic and experiential causes, some puppies may show more ominous signs at an early age (e.g., low fear and aggression thresholds). Evidence of excessive fear, irritability, and aggressiveness may reflect inchoate epigenetic processes, possibly prefiguring adult aggression problems (see *Behavioral Thresholds and Aggression* in Volume 2, Chapter 8). Puppies exhibiting such behavioral signs should be identified as early as possible and provided with appropriate supportive training and behavior therapy. Adult aggression problems depend on both genetic and experiential factors to incubate. Although genetic influences may put a dog at risk of developing a serious aggression problem, the risk can be significantly reduced by the presence of ameliorating or protective influences (Figure 6.3). In contrast, adverse social and environmental influences may significantly increase a dog's risk of developing aggression problems.

Competitive Social Excesses

Arguably the most common reason for seeking behavioral advice and training is aggressive play, including mouthing, biting, and chase-grabbing activities (see *Play and Aggression* in Volume 2, Chapter 8). Competitive playful excesses do not appear to be significantly correlated with adult aggression problems (Goodloe and Borchelt, 1998); however, such behavior may forecast oppositional tendencies, hyperactivity, and various discipline problems, stressing the importance of early behavioral training to head off secondary

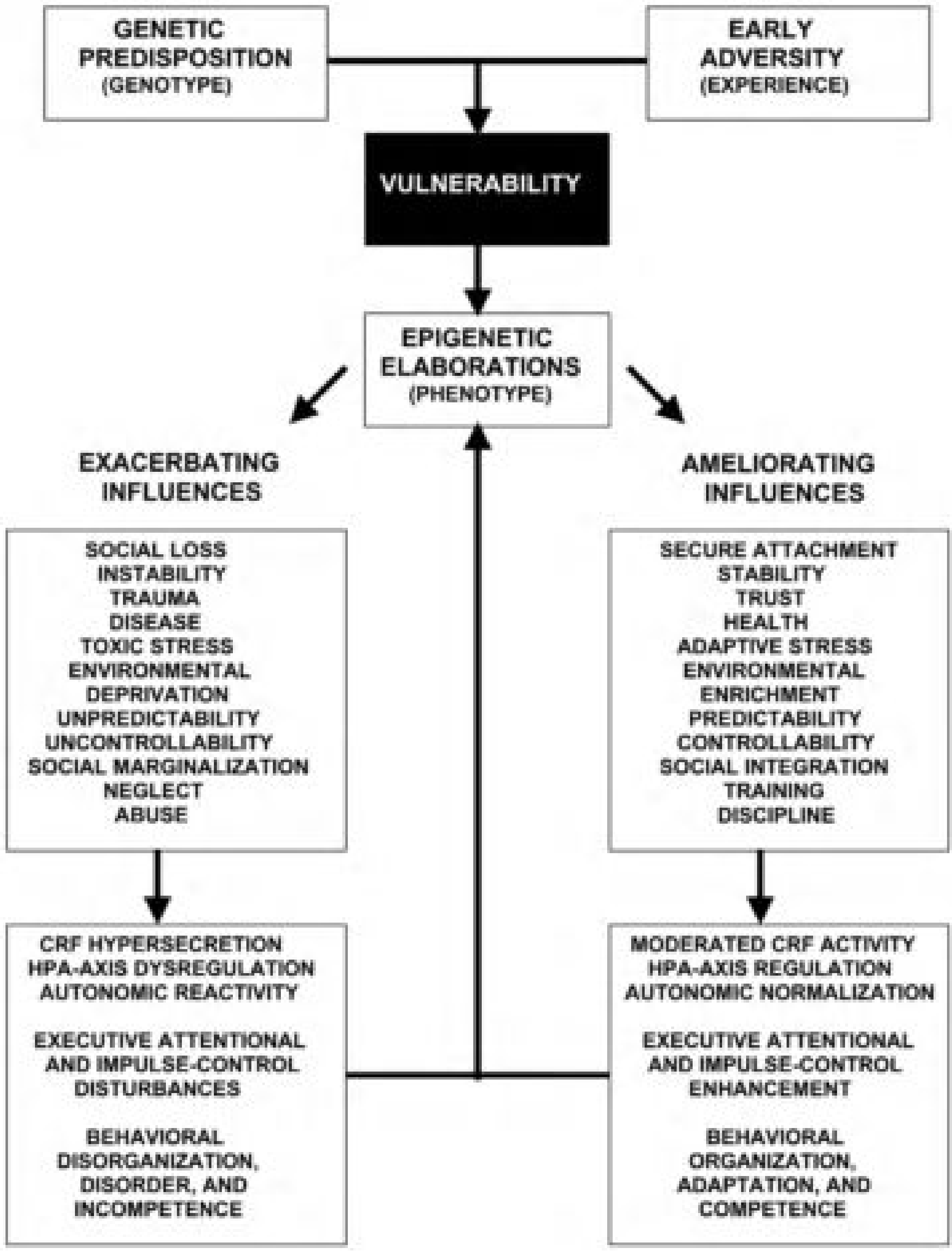

FIG. 6.3. Biogenetic and developmental predisposing influences may make a dog vulnerable to exhibiting aggression or other serious behavior problems in adulthood. Such problems are not inevitable, however, since subsequent experience (epigenesis) exerts a pronounced influence on how the predisposition manifests itself, determining whether a stable or unstable behavioral phenotype emerges. Serious behavioral problems are expressed through several layers of causation (biogenetic, ontogenetic, and epigenetic), resulting in physiological, neurobiological, and behavioral changes. Ameliorating influences may exert a protective effect against the development of aggression problems, whereas exacerbating influences place a dog at greater risk. CRF, corticotropin-releasing factor; and HPA, hypothalamic-pituitary-adrenocortical.

problems associated with excessive or disruptive competitive behavior. The key to successful puppy training is to occupy the puppy with structured play and positive learning activities. Even in cases where signs of aggression are not evident, training puppies to actively defer to human leadership should still be a prominent aspect of everyday handling and socialization. Many puppy problems involving overactivity and excessive playfulness can be rapidly improved by a combination of play therapy and increased opportunities for exercise.

The causes underlying disruptive competitive behavior are numerous and varied. Social learning is undoubtedly a factor, but difficult puppies may also be affected by a genetic predisposition and temperament traits that compete with the acquisition of behavior needed to adapt successfully to the home environment. In addition to reduced thresholds for fear, frustration, irritability, and aggression, some puppies appear to exhibit an inability to achieve sufficient reward stimulation from everyday activities (see *Neural and Physiological Substrates* in Volume 2, Chapter 5). These puppies cannot seem to get enough attention and contact and may be driven by an exaggerated and insatiable appetite for reward gratification. Stimulation-seeking puppies exhibit excessive attention needs, impulsive competitive tendencies, signs of inappropriate appetitive interests (pica), and an overall inability to achieve a normal degree of gratification and contentment from reward-producing activities, suggesting a developmental reward-processing deficiency. In such cases, it is especially important to use methods emphasizing positive reinforcement and ICT. Unfortunately, disruptive puppies are often treated with abusive physical punishment. Although limit-setting actions and TO may be useful, physical punishment involving the slapping or hitting of difficult puppies should be avoided. Most puppy owners are searching for answers that will give them enhanced control without resorting to abusive or excessively aversive techniques.

Mouthing, biting, and pawing on hands and clothing are common puppy nuisances. These playful competitive habits are normally acquired as the result of play fighting between littermates. Playful sparring and other contests involving the use of the mouth and feet constitute the most frequently observed active interactions between puppies. This playful interaction serves many vital functions, ranging from physical and sensory development to the elaboration of various social and competitive skills. Much of what puppies do during play facilitates learning how to use ritualized threat and appeasement displays competently. An important function of competitive play is to ritualize aggressive contests, thereby bringing about a more or less stable social organization among littermates. Puppies learn how to restrain their aggressive impulses and bite in order to perpetuate the joys of play. Under the influence of competitive play and social feedback, a puppy learns to be affectionate and restrain its aggressive impulses toward its playmates. In several respects, the interactive dynamics embodied in the litter are prototypical social behavior patterns exhibited by adult dogs and wolves. Playful fighting allows canine competitors to practice skills that might otherwise result in injury, increase social conflict, or disrupt the unity of the group. Puppies are conditioned to play fight affectionately, and significant benefits for the human-dog relationship may be obtained by engaging them in structured play activities.

However, some puppies may develop a rather compulsive interest in competitive behavior, engaging in persistent rough mouthing and biting whenever handled by the owner. Even though the presence of heightened excitability and competitiveness does not necessarily prefigure adult aggression problems, it appears to represent a significant risk factor (Guy et al., 2001) that warrants training and preventive efforts introduced at an early age. Competitive excesses may make puppies less enjoyable and adversely impact on the bonding process. A competitive puppy may intimidate children, frustrate adults, and create significant household tensions, gradually becoming the object of escalating punishment. Owners seeking help with disruptive puppies are often distressed and worried about the behavior. Some owners may express regrets about having obtained a dog, further emphasizing the potential injury that such behavior can have on the developing bond

between the family and puppy. Instead of moving toward the center of family life, a highly excitable and disruptive puppy may be swept outward on a trajectory of progressive rejection and isolation. Instead of spending constructive time with the family as a source of affection, comfort, and entertainment, a difficult-to-control puppy may spend the majority of time in a crate, behind gates, or kept outdoors. Under such circumstances of excessive confinement and isolation, a puppy's undesirable behavior may worsen and threaten to result in its removal from the home unless something can be done rapidly to ameliorate the situation.

Restrain and Train

Obviously, it is critical to offer such families immediate and effective means for establishing control. Suggesting that they keep the puppy on a leash while indoors can be extremely beneficial. Surprisingly, many inexperienced dog owners may not have thought of this simple solution. For disruptive and hyperactive puppies, the leash facilitates control by means of passive restraint, response blocking, and limit-setting directives. Overly active puppies appear to learn much more effectively and rapidly when the range of possible actions that they are free to perform is limited. Leash control limits the amount of behavior that fails while increasing the amount that succeeds. Rather than the owner engaging in pointless yelling and other reactive and ineffectual expressions of frustration, the leash offers a more direct and communicative means to establish control and guide a puppy's behavior. In an important sense, the leash represents a reification of the human will, helping to constrain and conform the puppy's behavior toward a more acceptable social ideal. Actions prompted by the leash can be reinforced and brought under the control of vocal signals. For example, stepping on the leash can easily block common jumping-up excesses. Pairing the word "Off" just as a puppy attempts to leap up becomes associatively linked with the thwarted action. Combining such mild avoidance training and response-blocking techniques with positive reinforcement of alternative behavior, such as standing or sitting, encourages puppies not to jump up when excited or seeking attention. Instead, puppies learn that obtaining attention or contact is best achieved by waiting or sitting or by exhibiting some other behavior that has worked in the past to produce positive reinforcement.

In addition to leashing puppies, tie-out stations can be set up throughout the house, especially in places where family members frequently gather to spend time together. Tie-out stations can be particularly useful for children, who might otherwise be overwhelmed by an overactive and uppity puppy. Such restraint provides sufficient control for them to get close to the puppy to feed it small treats by hand, pet it, and play with a toy. Initially, the puppy is trained to lick a closed hand to produce a concealed treat. As the puppy licks, the child can say "Kiss" and "Good puppy," thereupon giving the puppy the treat. In addition, with very little instruction, the puppy can be taught to sit and lie down by closely following the child's closed hand and getting a treat after completing the action. If the puppy becomes overly active or intrusive, the child can simply scoot back out of the puppy's reach, thereby initiating a brief nonexclusionary TO. As the puppy subsequently calms down, the child can return and continue the gentling process. Under the influence of such contingent pressures, the puppy soon learns that excessive or intrusive behavior results in the withdrawal of contact and the opportunity to obtain more food and affection, whereas self-control and cooperation result in the resumption of contact and the chance to get more food and attention. For puppies that engage in persistent mouthing or precocious aggression problems, more assertive procedures may be necessary. An active-control line can be set up enabling the trainer to turn the puppy away and restrain it at a distance for a brief TO period before allowing it to approach again and initiating reward-based training activities incompatible with biting. If the puppy engages in the undesirable behavior, it can again be turned away briefly (e.g., 20 to 30 seconds). Play activities, orienting and attending training, sit-stay, and down-stay training can be highly

effective in helping to organize the behavior of such puppies.

Learning to Succeed

All normal dogs strive to optimize their control over the social and physical environment in order to attain adaptive success and security. Fundamentally speaking, behavior is purposive and organized to achieve some useful goal, usually involving the enhanced prediction and control over significant attractive or aversive environment events. Consequently, behavior is selected (punished or reinforced) in accordance with its relative success or failure to predict and control significant events: behavior that fails is modified, extinguished, or suppressed, whereas behavior that succeeds is perpetuated. Obviously, success is preferred over failure, but failure is not without benefit. Without Pavlovian prediction errors and instrumental failures, learning to predict and control the environment would not proceed efficiently. Prediction errors and failures provide information that can be used to improve future efforts, which ultimately serve the purpose of enhancing an animal's adaptive success. Nonetheless, dogs do not set out to fail when they purposively interact with the environment, and when they do fail to predict or control some significant event causing them loss or discomfort, they may experience a variety of hedonically aversive emotional states (e.g., disappointment, irritability, frustration, anxiety, or fear). Normally, behavioral efforts that fail are usually followed by additional attempts and variations emitted under the potentiating influences of frustration or fear. Depending on a puppy's temperament and motivational predisposition, the quickening influences of frustration and fear may result in either adaptive or reactive efforts to control the environment. Although some failure is instructive and beneficial for learning, excessive and persistent failure together with adverse concomitant emotional arousal may lead to attentional and behavioral disturbances. In the case of overly active and disruptive puppies, excessive frustration and anxiety may adversely affect their ability to adjust effectively. Structured play and ICT provide the puppy with events and activities that are highly predictable and controllable, giving it beneficial opportunities to succeed and to obtain the emotional benefits associated with success (e.g., elation). Nothing more consistently promotes enhanced well-being and contentment than repeated success with periodic surprises (positive prediction error).

Bond Considerations

The concept of dominance has received some criticism and revision in recent years, especially as it regards the human-dog relationship (see *Concept of Dominance* in Volume 2, Chapter 8). Despite some significant limitations, the notion of social dominance remains a useful and viable construct. The positive implication of social dominance is that the owner must establish sufficient authority to limit a puppy's behavior and guide it into more appropriate directions. Most disruptive and socially competitive puppies are in search of a leader and a relationship based on cooperation and safety. In contrast, many dog owners are in search of an affectionate care-bond object. The end result of these divergent interests is often confusion, conflict, and discontentment. To succeed, the owner must defer care-bonding needs to the establishment of appropriate social limits and rule-based interaction with the puppy, whereupon care bonding naturally follows as the result of the nurturance during the training process. For its part, the puppy must learn to willingly submit to owner directives and to take pleasure from following the owner's instructions, a process that is facilitated by the presentation of affection, play, food, and other desirable things to the dog in exchange for its cooperative behavior. Social dominance does not imply, nor necessitate, rigid and hostile actions, nor does submission entail fear. Healthy dominant-subordinate relations, in fact, are characterized by a relative absence of overt aggression and fear. Although the assertion of dominance may include assertive gestures and ritualized aggressive actions, the intent of such behavior is not to evoke excessive fear. Similarly, the fawning body postures and submissive displays of the subordinate may overlap topographically with behaviors expressive of fear, but fear does not properly

characterize the motivational significance of such behavior. Both the dominant and subordinate partners appear to be influenced by affection for each other, with anger and fear being effectively constrained, thereby limiting overt aggression and other escape reactions associated with aversive emotional arousal (see *Affiliation and Social Dominance* in Volume 2, Chapter 8). Living in close social contact with each other, frequent and intense exchanges of aggression and reciprocal defensive behavior would be highly stressful and energy consuming for both the dominant dog and the subordinate. In an important sense, both the dominant dog and the subordinate are benefited by an affectionate impulse leading them to cooperate and tolerate close interaction with each other. The dominant dog's threats are tempered by increasing affection and familiarity, stimulating protective tolerance and responsibility for the group. Any fear that the subordinate may feel in response to the dominant dog's assertive displays is offset by a growing affectionate need to maintain contact in a search of social comfort and safety, a tendency facilitating a following and cooperative social role. In essence, establishing dominant-subordinate relations is a matter of enhancing mutual tolerance and affection for the sake of the greater good and benefit of the group. The subordinate's submissive displays may function as an escape/avoidance strategy aimed at evading the dominant dog's wrath, while at the same time stimulating its nurturance and protection.

Play and Leadership

Cynopraxic training promotes a balance of dominance, leadership, and nurturance in order to promote a healthy and successful human-dog bond (Figure 6.4) (see *Dynamics of Bonding: Nurturance, Dominance, and Leadership* in Chapter 4). A natural way to facilitate this process is through structured play activities. Leaders are not threatening or provocative; they are playful and fun. Just as assertive and submissive displays are modulated by affection, play activities similarly involve the exchange of behavioral sequences under the influence of affiliative motivations. Play activities early in life prepare dogs to advertise and acknowledge assertive and submissive displays in a socially constructive way, facilitating an affectionate and harmonious social existence. Protoplay activities emerge almost as soon as puppies can walk (Cairns, 1972). The ascendant emotion controlling play is joy, making playful interaction highly rewarding and conducive to the enhancement of social affection, competence, and trust.

Play is unique in that it has no apparent goal other than the perpetuation of itself, perhaps as the result of play-activated reward circuits producing elation and exuberance, even in the absence of a play companion or object. Young dogs commonly exhibit various forms of solitary play. In addition, some dogs exhibit a form of frenetic solitary activity, perhaps functioning as a compensatory release in situations providing insufficient opportunities for play. The spectacle may cause first-time dog owners to suspect that their dog has momentarily lost its mind. Dogs exhibiting such behavior appear to be possessed by a torrent of spontaneous locomotor impulses. They rush about as though careening around obstacles or fleeing from a nonexistent pursuer closing in from behind. Occasionally, a dog may appear to scramble forward faster than its body can follow, creating a hunched-up appearance as it steers wildly along its fre-

FIG. 6.4. Effective training promotes a balance of dominance, leadership, and nurturance. Dominance involves the imposition of appropriate limits on a dog's behavior in order to reduce socially intrusive excess and oppositional behavior. Leadership, on the other hand, shapes effective social behavior by means of structured play and integrated compliance training. The appetitive and social rewards used to support leadership contributes a nurturing aspect to the cynopraxic and training process.

netic path. As the playful release reaches a climax, the dog may display a wide open-mouthed smile, wedging its ears back. Meanwhile, like the baton of a drunken conductor, the tail wags excitedly one moment or, depending on the dog's passing mood and fancy, may be pressed up between its legs as though protecting it from the jaws of an imaginary pursuer. To my knowledge, a formal term has not yet been given to this kind of play behavior, but, given its solitary, spontaneous, and undirected character, perhaps the term *soliludic* would be a good choice. Soliludic activity nicely combines the Latin elements *solus* (alone) and *ludic* (spontaneous and undirected play).

Competent social play between people and dogs is expressed in two general forms: competitive and cooperative. Competitive play usually involves some element of contest (e.g., tug games and wrestling), whereas cooperative play involves sharing in the pursuit of some common activity (e.g., retrieving games). These functional aspects of play reflect the complementary dynamics facilitating harmonious group social organization and activity. Although excessive or agitational play may enhance undesirable behavior in dogs (see *Inappropriate Play and Bootleg Reinforcement* in Volume 2, Chapter 2), structured play in moderation may be highly beneficial. Tug-of-war games have been considered problematic with respect to the facilitation of dominance tensions, but little evidence supports the assumption that such games result in an increased risk of aggression in dogs not already exhibiting aggressive tendencies (Figure 6.5). Rooney and Bradshaw (2002) have attempted to test the effects of competitive play on dominance and other social behaviors. They exposed 14 golden retrievers to brief (3 minute) tug-of-war bouts involving 40 contests over 2 weeks. During the tests, the dogs were allowed to win at least two-thirds of 20 bouts and caused to lose at least two-thirds of the remaining 20 bouts. The authors found that such play had little effect on confidence levels (a measure they equated with dominance), even though the dogs reportedly became more playfully attentive, socially intrusive, and demanding as the result of repeated competitive play bouts. Observing that the win-lose outcome of tug contests had little effect on confidence levels, the authors concluded that, at least among the group of dogs tested, human-dog play is not a "major determinant of dominance relationships" (175). A number of problems with this study deserve mention. First, the assumption that brief tug-of-war contests are enough to alter canine social behavior significantly or, more specifically, that the differential effect of winning or losing such tug contests is capable of producing significant modifications of relative social dominance is highly questionable. Consequently, just because the study failed to detect a measurable effect does not necessarily mean that more lengthy or frequent bouts of tug-of-war, perhaps performed in a more agitating fashion, would not produce significant change in such behavior. In any case, the puppy is not really winning, but is being permitted to win and compelled to lose; the

FIG. 6.5. *A Tug of War* by W. J. Hardy (1891). Tug-of-war has long been a popular play activity between people and dogs. Although shunned by some trainers as being instigative of aggression, no compelling evidence links the activity with aggression problems in dogs. Competitive games can be a potent way to facilitate controlled aggression in the case of working dogs, but special agitational techniques are used in combination with ludic incentives to achieve such ends.

handler remains the locus of control throughout, that is, the play partner maintains their control status or social dominance whether the puppy wins or loses. Second, since the experimenter performing the tug contest was relatively unfamiliar to the dogs and not a member of their primary social system, such playful interaction probably did not denote the same social significance for them as it might if performed by a family member. In fact, under the parameters of the study, competitive play may be irrelevant to the dogs' social dominance interests (if such interests, as defined by the authors, exist) and, as the authors point out, may only lead the dogs to view the experimenter as a "favourable play partner" (175). Third, the experiment appears to be inadequately controlled to show that the independent variable (tug-of-war) is exclusively responsible for the behavioral effects observed. To show a causal relationship, the concurrent effects of increasing familiarity would need to be experimentally separated from the effects of tug-of-war, an experimental objective that would require the inclusion of additional control groups, a larger number of dogs, a functional and quantifiable (i.e., operational) definition of social dominance and a set of unambiguous interactive markers identifying it. Fourth, in any case, social dominance is probably a nonstarter with respect to puppy behavior and interaction with people. Puppy behavior appears more accurately described in terms of changes involving relative social subordination or dependency/attachment levels. Most puppies are happy to be obligate subordinates, exhibiting a high degree of dependency toward the owner and others, whom they seem to view as parental surrogates—not social adversaries.

In addition to learning about one another, play appears to help individuals learn to restrain immediate competitive self-interests for the sake of advantages resulting from social cooperation. To maximize the therapeutic benefits of play, it is necessary to structure play activities carefully. Dogs are responsive to a variety of play signals, including facial (play face), postural (play bow), and vocal expressions dedicated to the solicitation of play (see *Play and Aggression* in Volume 2, Chapter 8) (Rooney et al., 2001). In combination with the play face and bow, dogs may use a huffing or rapid panting sound to indicate playful intentions (Fox, 1971). Pere Bougeant (1739) long ago recognized the capacity of dogs for laughter and joy in association with play:

> Is it not evident that beasts laugh very heartily? See a couple of young puppies romping together in a field, catching, toying, and fighting one another in jest. Can all this be done without laughing? Is it essential to laughing, that it be done, as in man, by a motion of the lips and mouth, with a convulsive sound of voice? Laughing is no more than an expression of joy, and that expression is necessarily different in the different species of animals. Man laughs after his own manner, and the dog after his. No matter whether it is by a sudden bursting of the voice, or by a simple motion of the ears or tail, or by some other like expression. (196)

Recently, Simonet and colleagues (2001) made recordings of these play sounds and found that playing them back to young dogs evokes a heightened readiness to engage in play behavior. Fox reported that, the play sound (e.g., hhuh, hhuh, hhuh) was imitated, dogs became highly aroused, causing them to withdraw, bark, or solicit play. The panting sound may serve to elicit generalized arousal and, when combined with play signals, help to educe play behaviors. Repetitive sounds appear to evoke increased activity in dogs (see *Sensory Preparedness* in Volume 1, Chapter 5), a finding that is consistent with the notion that such sounds may play a role in the process of evoking play behavior.

All episodes of play should have a clearly defined beginning and end. Normally, it is best that some object be the focus of play. A tennis ball with a handle is ideal for this purpose (see *Training and Play*, Chapter 1). A small amount of an odorant (e.g., orange or orange-lemon) can be put inside the ball, perhaps helping to generalize playful associations to other contexts and thereby helping to lower play thresholds. Although structured competitive play is beneficial, highly arousing or provocative tug-of-war games, associated with growling and hard sustained biting and snapping at the toy, may result in accidental scratches and bites. Competing over a tug object produces frustration, causing the puppy to pull harder and more aggressively. Systematically raising frustration levels or

introducing an agitational element (e.g., tweaking) during bouts of competitive play can lead to an excitement overload in some dogs, perhaps precipitating an aggressive episode. This sort of behavior occurs and warrants appropriate precaution, but it is not the norm, and its occurrence may indicate the presence of significant emotional conflict, reactive dysregulation, or socialization deficits. When a trainer escalates the intensity of such behavior in conjunction with a puppy's increasing frustration and irritation, the puppy may learn to increase competitive output, becoming progressively tenacious and fearless. Under the influence of skilled training, such playful behavior can be gradually shaped into more serious and controlled aggression (e.g., police-dog training). Not fully recognizing the potential risks involved in playful competitive excesses, inexperienced dog owners may inadvertently promote excessive competitiveness in predisposed puppies. Despite the risks when improperly performed, tug games appear to provide a constructive outlet for competitive play, as stressed by Borchelt (1984):

> Although most puppies do growl during these games, it is a "play-growl" of quite different tone, intensity and significance than growls exhibited in an aggressive context. Conducted properly, the tug of war game will exhaust play behaviour and teach the puppy that mouthing and biting occur only with the toy in its mouth. Moreover, the interaction with the puppy (holding and pulling on the toy) eventually can be presented in brief bursts such that play is used to reward short durations of quiet, non-play behaviour. (172)

Enhancing the Leader-Follower Bond

Among young puppies, social relations and interactive boundaries are only loosely defined, exhibiting significant fluctuation and instability. As a result, hierarchical social distance between littermates may be weakly developed or vague, perhaps explaining the high levels of playful competitive interaction that typically occurs between them. The quality of early social competition appears to exercise a pronounced influence on how a puppy will later interact with people and other dogs after it is homed. As a consequence of early socialization experiences, most puppies come into the home with a set of established biases about what to expect from contact with others as well as possessing a well-practiced repertoire of playful competitive skills. The young dog does not naturally know or respect human social boundaries, but must learn directly from its interaction with people what is, and what is not, appropriate. The mother has given her puppies a solid foundation for inculcating such social learning, but everything depends on the owner taking over this canine educational process.

Upon coming into the home, the puppy may show a definite inclination to continue behavior that it has already learned and to refine its competitive skills further, often at the expense of the hands and clothing of family members. Since playful competitive activities appear to be highly reinforcing for puppies, it is of utmost importance that such behavior be blocked and redirected into more appropriate outlets. This is sometimes a hard-won step in a puppy's social education, but one that most certainly must be taken in order to ensure that the puppy becomes a welcome member of the family. To achieve this goal, the owner must provide the puppy with structured guidance, limit-setting directives, and positive instruction. Unfortunately, this process of social learning and adaptation is one that is commonly neglected, either as the result of misunderstanding or poor advice. Instead of becoming the object of affection and deference, the owner, failing to achieve the necessary social distance to become a leader, becomes a target of inappropriate social excesses. Owner contact needs, permissiveness, and tolerance provide an environment in which competitive behavior becomes exaggerated and progressively more difficult to control. In relatively gentle breeds (and individuals), the detrimental effects of such interaction may be limited to disrupting the leader-follower bond and impeding the acquisition of basic lessons needed to adapt harmoniously to life with people. However, in the case of more aggressive breeds and individuals, failure to exercise appropriate discipline, impose social distance, and assert leadership prerogatives may produce long-lasting and potentially serious consequences.

Establishing leadership does not entail or imply the use of hostile or provocative actions to dominate a puppy. Stimulation of excessive fear is counterproductive and destructive of social cooperation and trust. Scott (1992b) has argued that physical punishment is inappropriate for discouraging excessive competitive behavior in puppies. Instead of applying painful methods of physical punishment, he suggests that better inhibitory effects can be attained by the surprisingly simple means of restraint:

> In some of our experiments with dogs, we reared hundreds of puppies without using punishment, and were never attacked by them. What we did was to pick up the puppies almost daily, for various reasons. This began long before they were able to resist or fight, and they formed strong habits of relaxing peacefully in our arms. We could even break up a dogfight by picking up one or both of the contestants. (15)

Although submission and fear share some motivational overlap, they possess very different functional characteristics. In general, fear represents an adverse side effect of inappropriate techniques used to inculcate a subordinate attitude.

Good Things Must Be Earned

Among the most important lessons for oppositional puppies to learn are that *good things are better when earned* and, secondly, that *waiting is a canine virtue*. These central themes of puppy training entail that the desirable outcomes be made contingent on compromise and cooperation, in accordance with what Voith calls the Nothing In Life Is Free (NILIF) program (Voith, personal communication, 2002). The strategy includes controlling access to food, affection, exercise, opportunities for outings, play, and chew toys—in short, everything that a puppy may want can be used to shape more cooperative behavior. This training activity is integrated into everyday situations by exchanging rewards for compliance—thus the term *integrated compliance training* (ICT). Puppies should be trained from an early age to follow instructions and to develop a habit of compliant waiting, training that helps to form a solid foundation of impulse control for all future training and socialization efforts. In addition, young puppies can easily master basic obedience skills, such as walking on leash, sit, down, come, and stay. Training puppies to obey with positive incentives involving affection, play, and encouragement is much more effective and enjoyable for both the puppy and the owner than using force to compel cooperation and compliance.

Establishing a strong orienting response is an important first step. A squeaker is used to capture the puppy's attention and, just as it orients toward the trainer, a click is delivered and immediately followed by a flick of the right hand to the side. As the puppy approaches the bridge, "Good" is delivered and the hand is opened for the puppy to take the treat. This pattern is repeated again and again until the orienting response is strongly conditioned. The next phase involves pairing the squeak, orienting response, click, and "Good" with positive prediction error, whereby the size, type, and timing of the reward are varied to produce surprise. In addition, the squeaker sound is varied by squeezing it sometimes once or twice, sometimes firmly, sometimes softly, sometimes very briefly, and so forth. Sometimes, instead of having the puppy come back to the hand, the trainer tosses the treat to the puppy just as it turns its head. At other times, the treat is concealed under the last two fingers so that when the first two fingers open the hand appears empty, but then, just at the moment the puppy appears to recognize the discrepancy, the trainer says "Good" and opens the last two fingers to reveal the treat. Orienting and bridge training provide an anchor from which an almost limitless set of modules, routines, and patterns of tremendous variety and complexity can be trained.

DIFFICULT PUPPIES: ESTABLISHING THE TRAINING SPACE

Establishing a training space is achieved by setting limits on three common disruptive excesses: jumping, biting, and pulling (see *The Training Space* in Chapter 1). In addition

to limiting disruptive aspects of a puppy's behavior, this process results in the development of a beneficial degree of social distance between the owner and the puppy. Social distance emerges in the context of dyadic interaction and the formalization of social *roles* and *relations*. These social roles and relations are organized in accordance with various *rules* that govern the budgeted delivery of rewards and punishment. Intrusive excesses, such as biting and jumping up, behaviorally reflect a lack of organized social distance between the owner and the puppy—a necessary precondition for organizing rule-based roles and relations. Without the formation of appropriate social distance, a dog is prone to exhibit reactive social adjustments and develop an overly dependent attachment—not a harmonious relationship. On the other hand, extrusive excesses, such as pulling on the leash, strain the training space outwardly in the direction of attractive environmental stimuli competing for the puppy's attention and causing it to become distracted and pull. Fixing regulatory limits around intrusive and extrusive excesses is an essential step toward effective reward-based training efforts.

Pulling

A functional training space involving difficult puppies begins by training them to walk on a long line and a leash (see *Walking on Leash* in Chapter 1). Countless problems can be avoided or resolved by training puppies to actively follow the prompting of a leash. Pulling on the leash is inconsistent with the development of a healthy leader-follower bond and is productive of significant frustration and oppositional behavior. Pulling on walks has been associated with aggression problems in dogs (Podberscek and Serpell, 1997). Essentially, the leash is a physical representation or reification of the trainer's will. Instead of walking in a controlled and deferential manner, a pulling puppy is in continuous competition and conflict (opposition) with the owner for control. In contrast, a puppy that learns to walk with, rather than against, the owner appears to derive social bonding benefits from the exercise of increased impulse control. The reward-based techniques used to encourage slack-leash walking or controlled walking serve to enhance the leader-follower bond, improve attention, and increase impulse-control abilities. The puppy first learns to walk on a long line in the context of attention and recall training. A well-conditioned squeaker or similar attention-controlling stimuli can be used to override most distractions. Using a squeaker and clicker can rapidly help to shape the habit of walking on leash without pulling. For most puppies, a flat collar and leash is adequate, whereas, in the case of more assertive puppies that pull hard, a fixed-action halter can be very helpful. The clamping action of muzzling halters seems to produce unnecessary distress in puppies, and since there is no real need for such clamping action, a nonclamping halter is better suited for puppy-training purposes. Gradually, by limiting pulling and by selectively reinforcing appropriate walking behaviors, the halter control is eliminated. As with crate training, the goal of halter training is to get rid of the head halter as soon as possible.

Body Boundary

In practice, the training space is defined by the establishment of limits around biting and mouthing, jumping up, and pulling on the leash. Social limits are first set around the trainer's body. Both puppies and dogs should learn not to jump onto the trainer's lap, back, or arms, or leap at the face. As the body boundary is respected, puppies can then be trained to jump up on signal, as a reward for waiting and respecting the limit being set on the behavior. During social boundary training, puppies should be kept on leash. With the handler sitting cross-legged on the floor, any effort by the puppy to come up on the trainer's lap is countered with "off!" and a forearm block, as needed to prevent access to the lap. The force of the action is determined by need, with some puppies requiring very little direction and others requiring a more assertive impression. Gradually, the prompting action is delayed and faded to a slight movement of the fore-

arm as a warning, but the action may need to be reinstated if the puppy fails to respond to the faded prompt.

At the earliest sign of deference, the puppy is comforted and reassured with petting, gentle words, and food rewards (Figure 6.6). In the case of puppies showing a strong proclivity for biting on hands and clothing, a treat is held in a closed hand. As the puppy presses its nose against or licks the hand, the owner says "Good" in an affectionate tone and gives the treat to the puppy. This procedure is repeated with both right and left hands. Next, the puppy is encouraged to play tug with a tennis ball attached to a hand loop or other soft toys appropriate to the puppy's size and interest. After a brief tug game, a treat is offered to the puppy in exchange for the ball. When the ball is released, it is immediately thrown a few feet away and the puppy encouraged to retrieve it. As the puppy turns with the ball in its mouth, the owner should

FIG. 6.6 Feeding by hand and ball play.

flick the closed right hand (containing a food reward) to the side to attract the puppy's attention. The puppy is encouraged to hurry back and to release the ball ("Out") in exchange for a treat. Again, the puppy is encouraged to play tug, release the ball, retrieve it, and is rewarded with a treat concealed in a closed hand. Once the pattern is well established, vocal signals can be presented at appropriate points in the process to help bring the pattern under stimulus control. For example, just before the puppy turns, the handler should say its name and smooch; as the puppy moves toward the trainer, "Come" is spoken in a friendly tone and, finally, the trainer says "Good" just before giving the treat to the eager retriever.

At some point, the ball is left on the trainer's lap. If the puppy attempts to jump up to take it without invitation, the trainer asserts "Off," followed by a delayed slight forearm movement or thrust prompt, as needed to defend the boundary. If the puppy defers, it is given a treat by hand and the ball play is resumed; if not, appropriate blocking actions are repeated until the puppy actively defers to the body boundary again. Once the puppy shows a stable deference to the limit set around the lap, it can be given permission to come up by the trainer snapping thumbs and gesturing upwardly toward his or her body and saying "Hup" as the puppy is lifted onto the lap. Permission to get up on the lap is periodically given as a special reward. While on the lap, the puppy is petted, massaged, and vocally reassured. If the puppy begins to mouth, it is immediately pushed off and is let up again only after deferring to the biting rule. Such puppies can often be calmed by petting under the neck and on the chest between the front legs.

Jumping Up

In addition to controlling the body boundary while sitting on the floor, puppies should also learn to refrain from jumping up while the trainer is standing upright. Since jumping up is normal and friendly behavior that is acceptable under certain circumstances, the goal of training is not to suppress jumping up, but rather to bring the jumping response under

stimulus control, that is, establish a rule for its occurrence in the context of cooperative relations with the trainer. Puppies should be trained to jump up on signal (e.g., "Hup," with a thumb snap and upward movement of the hands) and to get off on signal (e.g., "Off," followed by downward movement of the hands). Puppies that jump up excessively can be trained with a differential reinforcement of other behavior (DRO) procedure, combined with a response-blocking procedure (e.g., stepping on the leash) and TO (see *Jumping Up* in Chapter 5). An alternative DRO training procedure involves delivering a click and treat after some variable but brief period (e.g., 2, 5, 3, 7, 2, and 3 seconds) and then occasionally dropping several small treats on the floor as a surprise. The treats should be very tiny and blend in with the flooring, thereby making it difficult for the puppy to find them. After dropping the treats, the trainer then helps the puppy locate them by pointing over the spots and making smooch sounds. Occasionally, as the puppy reaches the spot, the trainer might drop a choice treat, as though by accident, from the pointing hand to the floor. Dogs appear to have evolved an uncanny capacity to exploit our oversights, foibles, and clumsy moments, appearing to derive great pleasure when they do so successfully. The puppy is next trained to orient and make eye contact in response to its name, smooch, and click.

Once the foregoing introductory phase of training is carried out, the trainer should set the situation up in a way that the puppy might be tempted to jump up, but just as it prepares to do so, the trainer says "Off" in a firm buy quiet tone of voice. The trainer then abruptly glances to the side and tosses a treat to the floor in an exaggerated manner and then points until the puppy finds it. Next, the puppy is challenged to jump up with the challenge-dare "Do you want!" followed by a tap on the thigh or chest. But before the puppy has a chance to decide, the trainer says “Good” and tosses a treat to the side in the manner just described. Keeping the puppy on leash and stepping on the leash, as needed, in anticipation of the puppy jumping up can help to make this lesson easier to learn. For overly active and intrusive puppies, this procedure trains a habit of moving away from guests in response to the pointing signal and is good preliminary training for the go-lie-down exercise.

Mouthing and Biting

Like jumping up, puppy biting and mouthing on hands and clothing are usually playful social behaviors that have become excessive, often as a result of inappropriate control efforts or inadvertent reinforcement. Whenever possible, the best strategy is to shape gradually an acceptable playful outlet while simultaneously discouraging biting with means appropriate to the puppy's temperament and responsiveness to training. Although most puppies can rapidly learn to limit their tugging and biting to play objects, some may exhibit a persistent preference for biting on hands and clothing. Setting the lap and body boundary as previously described is a constructive first step toward controlling this common nuisance behavior. By establishing a body boundary, the owner can simply withdraw the hands to the safety of his or her lap, thereby setting up a response cost contingency to further discourage mouthing or biting. Also, various reward-based training procedures can be used to cause puppies to emit behavior incompatible with mouthing and biting. Puppies showing a strong oral avidity should be transitionally trained to interact with the owner via a toy (e.g., a ball or soft toy). The toy provides a triangulated object relation by which some of the puppy's playful social competitiveness and energy can be deflected or reorganized. In a sense, dog toys serve a similar function as transitional objects, as teddy bears do for young children. Dogs appear to treat toys as though they are partially animated, becoming joy-producing prey or objects of competition, especially as the result of interactive play with the trainer. Interactive object play appears to stimulate canine fantasy, mediating an object relation with the dog that the trainer can connect up with and guide to gradually transition the puppy toward a more realistic and rule-based relationship.

For some puppies, a startling tone of voice or expression of discomfort followed by the

introduction of some other activity (e.g., prompting the puppy to play a tug-and-fetch game) may be sufficient to control mouthing and biting excesses, whereas, in the case of more aggressive and competitive puppies, more assertive means may be necessary to discourage the activity. An active-control line can be used to turn the puppy away (TO) when it becomes overly intrusive and bites at the hands. As the puppy calms down, it can be called by name and tossed a ball to retrieve before being called back to engage in a bout of tug. Again, the amount of force used during such training is determined by a puppy's response and need. Often a reprimand ("Enough") or gentle prompt on the control line is sufficient to interrupt the activity and to turn the puppy's attention toward a more appropriate outlet (e.g., ball play). The prompting action should be sufficient to turn the puppy away, but need not be overly threatening or fear eliciting. Following such events, the trainer should challenge the puppy with the back of the right hand, held just in front of its nose, and in a daring and clipped tone state firmly "Do you want!" At such times, the puppy should yield an appeasement lick or avert its head, at which point the handler should reassure it with affectionate petting, gentle talk, and a food reward. Allowing the puppy to gnaw on a biscuit held so that only a small portion of it can be taken at a time provides a source of sustained reward, during which time the trainer can pet the puppy under its neck and chest. Subsequently, the challenge-dare can be used preemptively whenever there is an increased likelihood that the puppy is about to mouth or bite. The challenge can also be used to interrupt low-grade mouthing efforts. Whenever practical, mouthing on hands is best handled by reducing it gradually, granting the puppy some playful and affectionate mouthing allowance, so long as it shows a reliable willingness to defer when required to do so and it properly respects limits with regard to bite inhibition.

In the case of persistent or highly competitive puppies that escalate their efforts when thwarted, repeated 15- to 30-second TOs are used to reduce arousal and to discourage the behavior (see *Using Time-out to Modify Behavior* in Volume 1, Chapter 8). At the conclusion of each TO, the puppy is returned to the situation, prompted to sit, challenged, and reinforced with affectionate petting and other rewards, such as a tug-and-fetch game, when it defers. However, if the puppy attempts to bite instead, the trainer says "Enough, Time-out," and the TO procedure is repeated again and again (e.g., three to four times), until a de-arousal effect is observed. Rhythmic stroking on the neck and underside of the chest can also be helpful to induce a calming effect in many puppies. In some cases, a DRO procedure can be extremely useful as a means to moderate arousal levels. As control is established, a tug-and-fetch game can be offered as an alternative outlet for competitive play. In other puppies, an orienting response to a squeaker is formed in the manner previously discussed (see *Good Things Must Be Earned*). Once the squeaker is conditioned as a strong orienting stimulus, the squeaker can be used to interrupt mouthing. Just as the puppy stops, a click is delivered and a treat is given from a closed hand. To accomplish this training, the squeaker is held in the left hand under the last two fingers while the clicker is held between the first two fingers and the thumb. The back of the right hand is presented to the puppy and, as it orients, a click and treat is delivered. This pattern is repeated, and the puppy gradually learns to orient on the hand as a targeting stimulus. After taking food rewards, the trainer should pet and rub the puppy under its neck and chest. Repeated rewards involving food and petting appear to recruit a calming effect, perhaps via the conditioned and unconditioned release of oxytocin (see *Origin of Reactive versus Adaptive Coping Styles* in Chapter 4). As the puppy learns to follow the hand, it can be held over the puppy's head to prompt it to sit, moved downward to cause it to lie down, and so forth. The puppy is trained to sit, lie down, sit from the down, and stand from the sit, with vocal signals, bridge, and treat delivered at each step. If at any point the puppy attempts to mouth, the squeaker is used (sometimes softly and sometimes with a sharp squeeze) to interrupt the behavior, whereupon the trainer clicks, rewards the puppy, and initiates another series of basic training exercises or a tug-and-fetch game.

A collar control-and-thrust procedure can also be used in some persistent cases where less coercive methods have failed. The collar control is established by taking the leash at about 10 inches from the collar. The leash is wrapped once over the thumb and then gripped by closing the last two fingers of the left hand over it. Next, as the puppy continues to bite, the collar is abruptly taken with the right hand at approximately 4 o'clock and held with all four fingers closed around it. The left hand is then opened (except for the last two fingers holding the leash) and placed securely behind the puppy's head. Care should be taken not to grab the puppy's skin or fur while setting the collar control. With the collar control in place, the trainer makes direct eye contact and delivers a barklike reprimand "Enough," followed by a forward thrusting action. The thrusting action is delivered by tightening and immediately relaxing the muscles of the hands, arms, shoulders in an abrupt and concerted movement. If the puppy defers, it is then challenged to produce a submission response (e.g., appeasement lick or head-averting action)—behavior that is immediately followed by affectionate reassurance and petting. If the puppy escalates in response to the collar-control thrust, the control is released and the puppy is abruptly hauled off to TO. As the puppy defers and accepts petting without biting, the collar control is taken up periodically; however, instead of following it with a direct stare and assertive forward thrust, it is paired with affectionate eye contact, a smile, and rhythmic massage around the jaw muscles with the thumbs. In addition to reinforcing submissive behavior, affectionate petting and gentle talk can help to reassure the puppy that the handler remains a source of comfort and safety. At this juncture, a cycle of PFR training should be initiated. PFR training promotes relaxation and subordination to manual control (Figure 6.7) (see Appendix C).

Although hard mouthing and biting should be discouraged, the puppy should be gradually taught to mouth and bite on the hands in more gentle ways, by using the vocal signal "Gentle" to modulate the pressure of biting actions. Also, the puppy should be frequently encouraged to lick the trainer's cheek, or ear, with appropriate care taken and common sense exercised at all times to avoid taking unnecessary risks in this regard with puppies exhibiting unusually strong or aggressive mouthing and biting

FIG. 6.7 Puppy massage.

proclivities. Any nipping at the face should be promptly and firmly discouraged, while at the same times rewarding licking with sweet talk and an affectionate caress. Most puppies, even the most persistent and excitable ones, show a clear differentiation of behavior toward the hands and face. At one moment, they can be vigorously mouthing on hands, but immediately stop as the cheek is offered to them to kiss, whereupon they often lick or nibble at the ear, as well. Puppies that lack this apparent species-typical differentiation of biting and licking behavior—that is, biting equally on the hands and face—should receive intensive early training. Another developmental marker that should trigger concern and initiate appropriate training and socialization efforts is an active unwillingness to establish and to briefly hold eye contact (see *Social Engagement and Attunement* in Chapter 8). The presence of such behavior may represent a significant adjustment marker and should be the topic of future study.

Olfactory Conditioning and Excessive Biting

The introduction of an exciting food odor by a squeeze bulb can be useful in the control of some mouthing excesses that occur in association heightened emotional arousal. The activation of the olfactory system with the smell of an exciting food appears to exert a modulatory effect over the amygdala and hypothalamus, while strongly stimulating the ventral tegmental area, a brain area believed to play a prominent role in mediating reward. A strong-smelling cheese such as Romano or Parmesan can be cut into fine slivers and put inside a baby aspirator bulb. Sniffing the odor may interrupt the unwanted behavior briefly as well as perform an establishing-operation function, making the puppy more likely to show behavior previously conditioned with food reinforcement. For a hungry animal, the opportunity to smell food represents a significant incentive and potential source of reinforcement. With regard to the potency of appetitive olfactory stimuli, Long and Tapp (1967) found that hungry rats exhibit a pronounced increase in responding when reinforced with the smell of a familiar food:

> The response rates elicited by the deprived animals for the odor of powdered food were quite high in comparison with most other rewards. To the authors' knowledge, no other rewarding events, except electrical stimulation of the brain and escape from foot shock, have been shown to be such effective reinforcers when delivered on a similar schedule. (18)

In other cases, a novel odor can be delivered from a squeaker bulb or modified carbon dioxide (CO_2) pump. Orange and lavender appear to exert mild focusing and calmative influences on many puppies; chamomile, ylang-ylang, and sandalwood also appear to be useful, but adequate research is lacking. The fragrant odor appears to produce an abrupt, if only temporary, modulation of competitive tone, sometimes producing a rather dramatic effect when presented together with the squeaker or modified CO_2 pump (see *Olfactory Conditioning*). Olfactory control appears to work better when it is delivered in the form of repeated discrete odor puffs rather than as a continuous background odor. In addition to odors that appear to exert transient focusing and calming effects, odors can be used to mediate a conditioned inhibitory effect. A conditioned inhibitory odor is established by pairing a dilute odor (e.g. citronella-eucalyptus or eucalyptus-cedarwood) with the hissing sound of a modified CO_2 pump. The selected odor is diluted 1:30-50, and a small amount of it is dabbed on a cotton wad packed gently inside the base of a inflator needle that has had the needle removed (see *Compressed Air* in Chapter 2). The scented oil is blown out of the cotton into a tissue, leaving the cotton scented but dry.

The conditioning procedure is carried out by carefully squeezing the pump lever to release an inaudible or barely audible airflow, concealed from the puppy's view and directed toward the floor—not toward the puppy. The scented airflow is continued for approximately 2 to 3 seconds before a half-second puff/hiss of compressed air is delivered to interrupt mouthing (Figure 6.8). The startle used for such training can be very effective when delivered at relatively low levels of stimulation. The puppy is immediately challenged with the back of the hand, "Do you want!" If the puppy averts its head, the response is bridged and rewarded; whereas, if the puppy fails to

defer, the conditioned odor is presented again via a squeaker bulb (squeaker valve removed). If the puppy continues to mouth, a second conditioning event is delivered using a hiss/spritz level of compressed-air startle, followed by the same challenge-dare procedure. Once the puppy defers, the behavior is rewarded, and the puppy is brought up on the trainer's lap. If the puppy begins to bite or mouth while on the trainer's lap, the conditioned odor is delivered from a squeaker bulb, and it is pushed away. The challenge-dare procedure is performed and, if the puppy defers, it is rewarded; if not, the odor is delivered from the squeaker bulb, and the puppy is rushed off to TO, followed by training activities, as described previously. A crumpled tissue scented with the conditioned odor can be placed in the TO room in advance to further integrate the significance of the odor as an inhibitory signal. Once the conditioned odor is established, it can be used to produce a

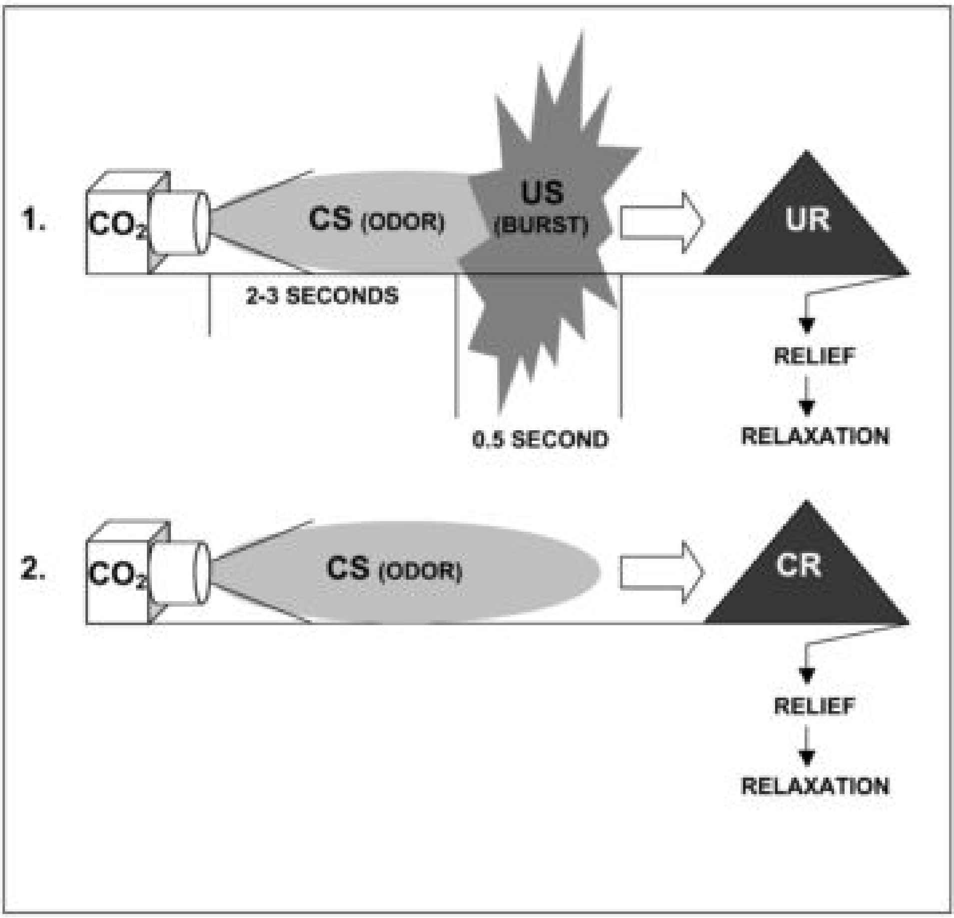

FIG. 6.8. Classical conditioning of odor and air burst. Odors are highly prepared for both appetitive and aversive classical conditioning in dogs. In cases involving persistent biting excesses not responsive to other training efforts, an olfactory conditioning procedure can be highly effective as a means to interrupt such behavior. After one or two conditioning bursts, the odor delivered at a low pressure or from a squeaker bulb (without the squeak mechanism) may cause a puppy to become more responsive to other control efforts. US, unconditioned stimulus; UR, unconditioned response; CS, conditioned stimulus; and CR, conditioned response.

direct inhibitory effect (Otto et al., 1997) or to potentiate other startle techniques (Paschall and Davis, 2002).

POSTURE-FACILITATED RELAXATION

Before coming into the home, the average puppy is exposed to a tremendous amount of competitive interaction with littermates, somatically attuning and sensitizing it to respond to tactile stimulation and manual control with increased arousal, excitement, and playful competitive behavior. In addition, the puppy may be accustomed to a high level of social stimulation no longer available to it, thereby triggering unwelcome attention-seeking excesses and intrusive competitive behavior. The owner may be confused and frustrated by the puppy's incessant search for stimulation and its prodigious appetite for competitive play, possibly leading to improper disciplinary practices, excessive crate confinement, and other practices inimical to healthy socialization and habituation. There is no justification for slapping or spanking an overly competitive or aggressive puppy, especially since such actions may only cause the puppy to retaliate with even more vigorous aggressive behavior or become progressively insular and avoidant. Threatening dominance procedures wherein a puppy is flipped on its back and pinned there against its fearful or angry protests should also be avoided unless necessitated by extraordinary circumstances requiring such restraint. Although occasional mild to moderate assertions of manual control may be expedient to avert an escalation of aggressive tensions, excessively forceful or threatening handling does little to inhibit aggressive behavior constructively. Such puppies should be provided with appropriate play and exercise, daily reward-based training, and routine limits set on inappropriate behavior via TO and response-blocking procedures. In addition, competitive and stimulation-seeking puppies should be exposed to graduated relaxation exercises aimed at reducing agitation and modulating competitive tensions. Instead of relying on excessively forceful or threatening tactics, submissive behavior can be gently and efficiently facilitated through graduated posture control and relaxation training, a process known as PFR training. When properly and routinely performed, PFR training produces several benefits (see *Basic Guidelines and PFR Techniques* in Appendix C):

1. Facilitates bonding process
2. Enhances trainability
3. Exerts beneficial counterconditioning effects
4. Promotes affection, cooperation, and trust

Taction and Posture-facilitated Relaxation

Tuber (1986) has emphasized the value of massage for promoting calmness and relaxation in dogs, advising that massage and training dogs to relax should be just as important as other training activities. Petting and massage have long been recognized as exerting significant effects on canine cardiovascular activity indicative of reduced sympathetic arousal (see *Effect of Person* in Volume 1, Chapter 9). Petting provides a potent source of reward for many dogs. Kostarczyk and Fonberg (1982) found that dogs that respond to petting as a reward exhibit cardiac deceleration while being petted, followed by rapid acceleration when petting is discontinued. The experimenters report that dogs failing to respond to petting as a reward exhibited cardiac acceleration when petted (Figure 6.9). These observations suggest the possibility that heart-rate changes in response to petting may provide useful diagnostic markers pertaining to contact aversion and proneness to irritability as the result of tactile stimulation. In the case of dogs that are responsive to petting as a reward, petting may induce sympathetic dearousal and cardiac deceleration via the recruitment of an antistress response (see *Oxytocin-opioidergic Hypothesis*).

Odendaal (1999 and 2000) has reported that close social interaction between people and dogs results in a cascade of neurobiological events that facilitate enhanced attachment and comfort. Close social contact and petting produce an elevation of circulating neuropeptides (ß-endorphin, oxytocin, and prolactin) and other neurochemicals believed to mediate pleasure (e.g. phenylethylamine), affiliative emotions, and social attachment. Oxytocin is

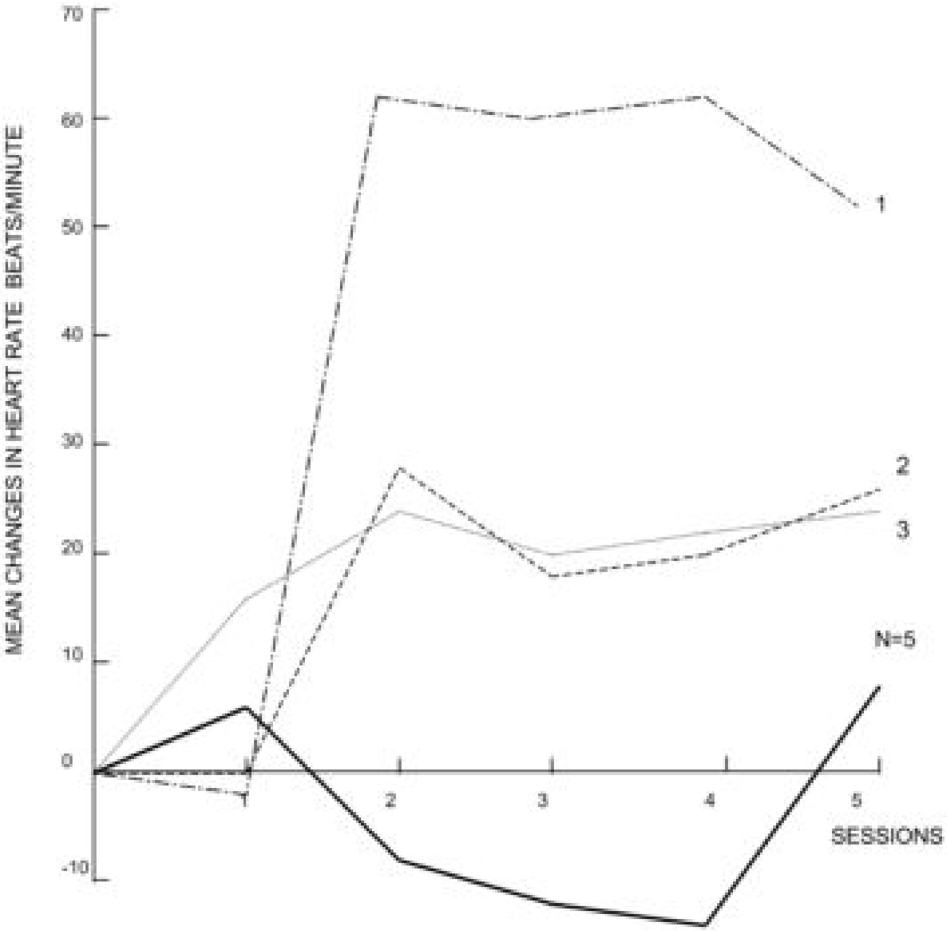

FIG. 6.9. When petting is effective as an instrumental reward, it produces a deceleration effect on heart rate. Dogs that do not respond to petting as a reward exhibit an opposite response. When petted, such dogs may exhibit pronounced heart-rate acceleration. The solid line shows the mean heart-rate changes calculated for five dogs that were responsive to petting. Broken lines 1, 2, and 3 indicate the acceleration effects of petting exhibited by three dogs not responsive to petting.

believed to actively mediate social bonding and to exert pronounced cardiovascular changes and antistress effects (Uvnäs-Moberg, 1998b), while exerting a potent diminutional effect over irritability (Lund et al., 2002) and aggression (Panksepp, 1998), "reducing all forms of aggression that have been studied" (257).

Hennessy and colleagues (1998) have reported that it is not just petting, but the way in which petting is done, that yields the best stress-reducing effects. They found that petting consisting of long, firm strokes produces the strongest effect on HPA-axis activity (Figure 6.10). Whereas light touch tends to increase arousal (e.g., tickling effect) or irritation, firm and continuous touch appears to produce a calming effect. Grandin (1992) has noted that deep-touch pressure (massage and firm petting) appears to alleviate the touch aversion exhibited by many autistic persons. Grandin, an autistic person, developed a "squeeze machine" to deliver continuous pressure over large areas of the body. She claims that the machine produces benefits, partly because one cannot pull away from it

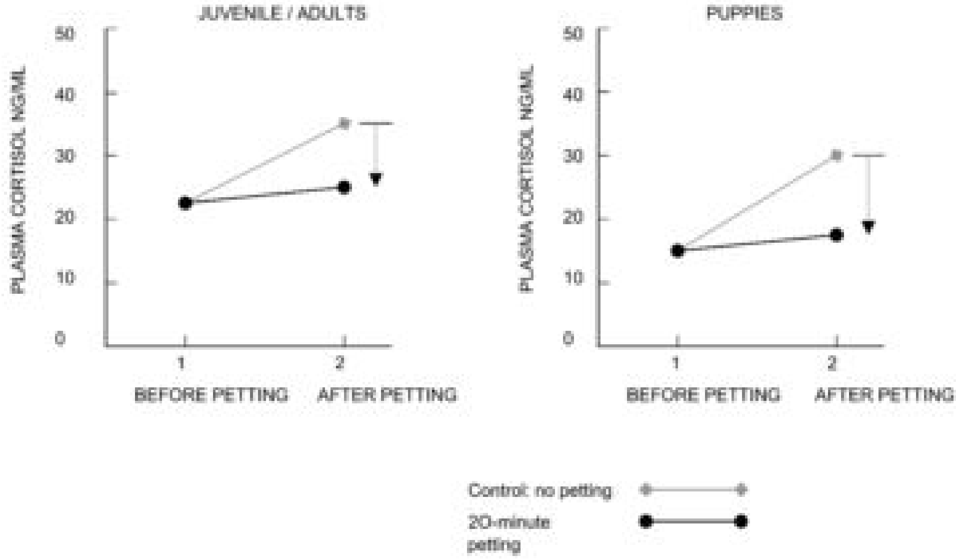

FIG. 6.10. Effect of petting on stress response to venipuncture. Petting involving firm, long, and slow strokes helps to restrain physiological stress when taking blood. Both control and petted groups had blood taken at point 1. Controls were returned to their kennels, while the other received 20 minutes of petting. Adapted from Hennessy et al. (1998).

(response prevention), making a previously aversive experience a more enjoyable one. In addition to becoming less aggressive and tense, she reported becoming more receptive of human touch and gentler in her own touching contacts with others, including a pet cat:

> Using the machine enabled me to learn to tolerate being touched by another person.... It made me feel less aggressive and less tense. Soon I noticed a change in our cat's reaction to me. The cat, who used to run away from me now would stay with me, because I had learned to caress him with a gentler touch. I had to be comforted before I could give comfort to the cat. (66)

Field (1995) found that premature babies given tactile stimulation consisting of light stroking failed to gain weight, whereas babies given massage consisting of firm stroking gained weight. In addition, Field and colleagues (1996) also demonstrated that massage therapy helps to alleviate stress-related physiological and behavioral symptoms exhibited by babies born to depressed mothers. Brief massage performed twice a week for 6 weeks significantly reduced cortisol, norepinephrine, and epinephrine levels while increasing serotonin activity. These physiological changes were associated with increased contact responsiveness and sociability in the infants. Massage has been shown to reduce anxiety and symptoms of depression in child and adolescent psychiatric patients, further reinforcing the value of massage as a therapeutic modality (Field et al., 1991). Gantt (1944) observed that petting exerted a potent inhibitory effect over conditioned anxiety in severely disturbed dogs (see *Tactile Stimulation and Adaptation*).

Posture, Response Prevention, and Posture-facilitated Relaxation

Together with supplemental environmental enrichment, exercise, play, daily training activities, and guided tactile stimulation, gentle manual control and restraint efforts help modulate a puppy's social competitive and stimulation needs. The aim of manual control is to shape behavior conducive to progressive submission and relaxation. Posture communicates behavioral intention and reflects under-

lying emotional and motivation states. Body posture and emotion exert a reciprocal influence on each other via somatic feedback. Consequently, the expression and experience of emotional states necessarily involve postural and gestural changes—*there are no disembodied emotions*. The manipulation of posture through guided controls, prompts, and position shifts is associated with the controlled evocation of a variety of emotional states. Response prevention assists in this process by blocking bodily responses incompatible with submissive relaxation. In addition, manual restraint exerts a pronounced calming effect and deceleration of heart rate—an effect that is magnified by petting and massage.

Gradually, instead of evoking competitive reactivity and resistance, the puppy learns to submit to handling as a source of increased comfort and safety. Response prevention and restraint assist in this process by blocking responses incompatible with submissive affection and relaxation. During the imposition of gentle manual restraint, the puppy is exposed to mild limit-setting actions (dominance) in the presence of the counterconditioning influence of massage and vocal reassurance. Postural restraint in combination with relaxing massage helps to reduce agitation by promoting more organized and compliant responsiveness to human control and manipulation.

Most puppies actively enjoy massage and accept PFR training without incident. However, in the case of difficult puppies, depending on individual differences, one of three typical responses to gentle manual restraint and massage may occur: submissive forbearance, competitive struggle, or efforts to escape. The manual restraint at such times should be consistent and clear but not overtly intimidating or threatening. Further, the level of force used to restrain the puppy should be immediately responsive to the puppy's willingness to defer. In cases involving extreme reactivity, preliminary desensitization and instrumental shaping procedures should be used first to encourage compliance and trust. The presentation of a fragrant odor (e.g., orange, chamomile, or sandalwood) may exert a useful calming or diversionary effect. Throughout the PFR process, the puppy is reassured and comforted with relaxing massage. The operative idea is to use response prevention and the accumulative effects of relaxing massage to help the puppy accept the next level of control with minimum reactivity, thereby improving its willingness to submit and, ultimately, achieving enhanced feelings of affection, comfort, safety, and relaxation. Over the course of several cycles of PFR training, the puppy learns to accept and enjoy the systematic, highly structured, and predictable manual control efforts composing the PFR ritual, becoming progressively relaxed and compliant. PFR training can be effectively incorporated into routine care and grooming activities. All puppies should learn to accept being brushed and combed, having their eyes and ears examined and cleaned, and having their feet handled and cleaned, and submit to nail clipping and filing. Massage-induced relaxation makes these grooming chores easier to perform and less stressful for puppies and dogs.

Canine Domestic Aggression

PART 1: SOCIAL COMPETITION AND AGGRESSION

INTERACTIVE CONFLICT, STRESS, AND SOCIAL DOMINANCE

Social dominance is frequently posited as a formative principle organizing social behavior. Animals living in close groups are hypothesized to regulate their social interaction and aggressive impulses in accordance with social rank and status. According to this model, the cumulative victories and defeats resulting from competition over valued resources gradually result in a hierarchy of dominant-subordinate relations. Rowell (1974), a primatologist, has criticized the social dominance hypothesis on several grounds and rejects it as a social organizing principle. Although often bordering on diatribe, her analysis offers a number of valuable insights pertaining to social relations and organization developing under the influence of stressful conditions. She argues that rigid linear dominance hierarchies primarily develop under the influence of unnatural and conflictive conditions. Rowell, arguing that subordinate animals most often initiate conflictive interaction, turns the social dominance concept on its head by positing instead a subordinance [*sic*] hierarchy. She suggests that conditions of captivity produce unnatural levels of interactive conflict and tension, increased aggression, and the dysregulation of the hypothalamic-pituitary-adrenal (HPA) system. The submission behavior of subordinates toward dominant animals is not reciprocated by affectionate tolerance (as might occur under natural conditions), but instead is met by aggressive threats and challenges. Instead of submitting and integrating friendly relations, animals living under such conditions appear to succumb gradually to stress and develop involuntary subordination strategies, thereby losing their capacity or desire to compete effectively. The long-term adverse effects of involuntary subordination have been implicated in the etiology of depression (see Gardner, 1982). As such, Rowell's subordinance hierarchy is an index of stressful reactivity and involuntary subordination, referencing an animal's ability to cope with stressful social conflict and environmental adversity with relative social rank. Under adverse conditions, animals showing a blunted response to stressful conflict (i.e., fearlessness/low cortisol) may obtain a competitive advantage over other animals exhibiting heightened emotional reactivity (i.e., fearful/high cortisol) and vulnerability to social and environmental stressors (see *Autonomic Arousal, Heart Rate, Aggression*, and *Stress, Low Cortisol, and Aggression*, in Chapter 6):

> Submissive behavior, on the other hand, can be related to hyperfunctioning of the adrenal gland in response to environmental stress, and occurs in its most extreme form in captivity. It seems that whereas adrenal responsiveness may

> be advantageous under normal conditions, the unusually high levels of stress encountered in captivity may lead to a higher-than-useful response level. Thus a rigid hierarchy may with some justification be regarded as a pathological condition of a society brought on by too high stress levels … Whereas the concept of dominance has apparently little to offer beyond its use as a shorthand description suggested above [predicting competitive outcomes], the concept of subordinance, as seen in submission hierarchies, may still provide helpful insights, especially in relating endocrine function to behavior. (Rowell, 1974:151)

According to the subordinance hypothesis, conflictive interaction initiated by subordinate group members results in varying degrees of HPA dysregulation and adrenal exhaustion, depending on each animal's ability to cope with the stress accruing as the result of repeated activation of the flight-fight system (FFS) (see *Social Competition, Cooperation, Conflict, and Resentment*). Rowell's hypothesis predicts that higher-ranking animals should show the lowest glucocorticoid levels, whereas the lower-ranking animals should show the highest glucocorticoid levels. A social organization based on individual differences with respect to their ability to cope with social stress is reminiscent of Calhoun's experiments (1962 and 1963); however, Calhoun's findings flatly contradict Rowell's assumptions concerning the functional significance of social dominance. Calhoun's research supports the necessity of a social dominance structure in order to promote social and territorial order, to facilitate physical health, and to increase reproductive fitness (see *Calhoun's Rat Universe* in Volume 2, Chapter 7). Under conditions in which social organization was based on social dominance, Calhoun found that stressful interaction and conflict were prevented or reduced (insiders), whereas under *outsider* conditions in which social behavior differentiates in accordance with each animal's ability to cope with stress, a state of social disorder and disintegration followed.

Rowell's hypothesis is probably better described in terms of involuntary subordination and mutual intolerance resulting from unfriendly exchanges between individuals operating under the socially disintegrative influences of conflictive arousal and reactive coping styles. Dominance by threat and attack and subordination by fear generates escape/avoidance behavior, aggressive reprisals, and resentment in association with the activation of the FFS and an involuntary subordination strategy (ISS). These reactive behaviors are neither dominant nor submissive but reactive coping styles operating under the influence of the FFS. Social interaction operating under the influence of the FFS tends to promote social intolerance, irritability, disintegrative discord, and hostility.

Fear-related behavior and obtrusiveness are explicitly excluded from the classical concept of subordination and submission as described by Schenkel (1967). Antagonism and fear are incompatible with the affectionate and affiliative intent of active and passive submission. Submission behavior is basically an expression of filial love and desire to achieve an integrated and harmonious relationship within the family/pack unit. Typically, aggression problems are not the result of a dog acquiring a dominant attitude toward the owner, but rather such problems most often stem from a failure of the owner to respond to the dog's submissive solicitation for dominant tolerance and care. Instead, the owner may respond to active-submission behavior with punishment by ignoring, confining, or hitting the dog, thereby prompting adjustments based on an ISS. In contrast, when the owner responds in a friendly and constructive way to active-submission behaviors, an affiliative process based on a voluntary subordination strategy (VSS) and the integration of a trust-based bond between the owner and dog is initiated. Dominance is solicited, if not elicited, by the care-seeking and begging (active submission) behavior of the subordinate. Schenkel nicely describes the nature of submission in dogs and wolves in a manner that resonates with cynopraxic objectives:

> We may conclude that submission is a contribution by the inferior to harmonic social integration on the basis of social hierarchical differentiation. It does not elicit a stereotyped automatic response. Integration asks for a contribution by the superior also, that is, tolerance. The superior's contribution may even exceed

submission in its competence to shape the social contact or relation. (325)

WOLF MODEL OF DOMINANCE AND SUBMISSION

Many problematic training strategies used to force submission by physical punishment are derived from the popular depictions of dominance and submission portrayed by Lorenz (1955). According to this view, submission results when an opponent is defeated; however, this notion appears to be relatively alien to the social organization of dogs and wolves. Mech (1999 and 2000) has strongly criticized this popular misconception of wolf social behavior and dominance. Drawing upon observations of wolves living under natural conditions, he argues that force-based concepts of social dominance are derived from the social behavior of wolves living under captive conditions. According to Mech, social dominance and submission is an integral aspect of wolf social behavior and family life. He rejects the notion of the "alpha" wolf, arguing that such an attribution is comparable to calling a human parent an alpha. Further, since wolf offspring are generally subordinate to the breeding pair, referring to the parents as alphas or the alpha pair is redundant and adds nothing informative to the picture. The term may still have descriptive value in the case of wolf relations formed within groups containing multiple families or the hierarchical relations formed by wolves living under captive conditions (Van Hooff and Wensing, 1987). The origin and meaning of social dominance in wolves is closely associated with reproduction, a division of labor, and the formation of cooperative and harmonious family relations (Mech, 1999). These cooperative relations serve to hold the family/pack unit together and are dedicated to the service of various basic survival and reproductive priorities, including the support and protection of progeny via group-coordinated hunting and defensive activities, occurring under the leadership of the alpha pair (Mech, 2000). In the wolf family/pack, reproduction and territorial defense are the prerogative of the breeding pair (Mech, 1970), further supporting the hypothesis that dominant-subordinate relations are closely tied to incentives associated with reproduction (Derix et al., 1993). The pack is usually little more than a family group, consisting of a breeding pair and progeny. As the result of parental socialization and food begging, the progeny are trained from an early age to exhibit active-submissive behavior toward the breeding pair and other adults, perhaps helping to account for the infantile characteristics of many submission displays. Although Mech rejects a rigid and "force-based dominance hierarchy" (Mech, 1999), he acknowledges that the breeding pair dominate and lead the behavior of their young (Mech, 2000).

The progeny are typically obligate subordinates with respect to the parents, upon whom they are socially and physiologically dependent. The social competition between progeny is organized from an early age onward around the control of valued resources. These sibling rights and privileges are maintained by the exchange of ritualized threat and appeasement displays and the formation of a social hierarchy that prefigures adult status relations (MacDonald, 1983 and 1987). Competition and dominance tensions (squabbles) appear mostly to involve transient situational disputes, especially involving contests over food. The reproductive and familial origin of social dominance is reflected in the reduced tendency of male and female wolves to fight with each other (Schenkel, 1967), with the male typically dominant over the female and the rest of the pack, while the female is dominant over all pack members except the male (Mech, 1999). As wolves reach sexual maturity, they eventually leave the natal group and join up with other dispersed wolves to reproduce and form new packs, thereby reducing the risk of disruptive competition within the group. Most wolves leave the family/pack before they reach 2 years of age, with virtually all of them dispersing before they turn 3 years of age (Mech, 1999).

DISPERSAL TENSIONS AND HOUSEHOLD AGGRESSION

Some forms of canine domestic aggression (CDA) may be related to the activation of dispersal-related tensions in adulthood. As previously discussed, wolves disperse between 1 and 3 years of age, a time frame that is fre-

quently cited as significant with regard to the expression CDA (Borchelt and Voith, 1996). Although the lupine dispersal instinct appears to be reduced in dogs by virtue of paedomorphosis, some dogs may express polymorphic variations that support dispersal tensions in association with the formation of overly exclusive and dependent bonds with one particular person in the household, perhaps setting the stage for persistent interactive tensions, intolerance, and a failure of affected dogs to integrate submissive and friendly relations with other family members. Hypothetically, under conditions in which dispersal and breeding activities are thwarted, social dominance, bonding, and symbolic reproductive imperatives may coalesce in novel ways, facilitating social dynamics conducive to asexual-pair bonding, thereby forming an *insider* satellite group within the family system. As a result, the dog may become increasing intolerant toward other family members and may threaten or attack them as intruding *outsiders*, thus symbolically dispersing and establishing a territorial boundary within the context of the home (e.g., a bed or the favored owner's lap). Such dogs may gradually threaten a husband or wife when he or she enters the bedroom or while getting into the bed. More rarely, the aggressor may threaten a parent who approaches or shows affection toward a child. These dogs often show exaggerated territorial behavior, becoming highly reactive and threatening toward visitors and strangers coming into the house or approaching them while in a car. Owners may be flattered by the dog's close attention, affection, and protectiveness, and may inadvertently reinforce it. These sorts of aggression problems are often surprisingly well tolerated by the household and held as something akin to an innocent idiosyncrasy, at least until someone gets seriously bitten. Frequently, it is the "protected" person who gives first blood while daring to restrain the dog during one of its aggressive episodes.

Dynamic Modal Relations and Social Dominance

Basic Concepts of Cynopraxic Training Theory

According to cynopraxic training theory, well-organized and functional prediction-control expectancies and coordinated emotional establishing operations are subject to refinement via the coding of positive and negative prediction errors (see *Basic Postulates, Units, Processes, and Mechanisms*, in Chapter 10). A prediction error occurs when a control expectancy is confirmed but in association with an unexpected result, such that the anticipated outcome turns out to be better or worse than expected. Such discrepancies between predicted outcomes and actual outcomes produce exciting or depressing cortical reward/punishment effects via an activating or suppressing effect on dopaminergic reward circuits (see *Classical Conditioning, Prediction, and Reward* in Chapter 1). Better-than-expected outcomes resulting in positive prediction error produce surprise (reward), whereas worse-than-expected outcomes resulting in negative prediction error produce disappointment (punishment). Outcomes that match prediction-control expectancies and calibrated establishing operations are verified (reinforced) and result in enhanced comfort or safety. Verified actions are referred to as *control modules*. Control modules are under the motivational influence of appetitive and emotional establishing operations calibrated to meet the anticipated needs of a dog as it acts in accordance with functional expectancies and control incentives. Control modules form routines and patterns of goal-oriented behavior within the context of adaptive modal activities. The collection of control modules, routines, and patterns of behavior formed in association with adaptive modal activity is referred to as *culture*. Control modules and routines are maintained by the gratifying and relaxing effects (somatic reward) produced by verifying prediction-control expectancies and calibrated establishing operations. These integrative learning experiences and adjustments occurring in accordance with positive and negative prediction error and verification are mediated by a complex network of comparator loci, set points, positive- and negative-feedback systems and regulatory neural networks hypothesized to operate at a preconscious level of cognitive organization. Control modules and routines that fail to produce expected outcomes result in the disconfirmation of the instrumental prediction-control expectancy and calibrated establishing

operation. Disconfirmed control modules are extinguished by means of a revised set of incompatible prediction-control expectancies and abolishing operations (see *Startle and Fear Circuits* in Chapter 3).

Adaptive Modal Strategies

Behavior operating under the influence of positive and negative prediction error is referred to as an adaptive modal strategy or coping style. There are two general adaptive modal strategies: active and passive. Active modal strategies develop in association with reward incentives resulting from positive prediction error, whereas passive modal strategies develop in association with efforts aimed at avoiding negative prediction error. Adaptive modal strategies develop in the context of organizing and refining the expression of emotional command systems. For example, active modal strategies operating in association with the seeking system include forward movement, searching, exploring, experimenting, probing, discovering, risk taking, and so forth, whereas passive modal strategies consist of stopping or backing, hesitating, waiting, delaying, ritualizing, and so forth.

Active modal strategies are supported by reward incentives associated with positive prediction error, surprise, novelty, and enhanced arousal and excitement. As such, active modal strategies operate in accordance with what Gray (1990 and 1994) refers to as the behavioral approach system (BAS). Adaptive modal strategies incorporate and organize control modules, routines, and complex patterns of behavior. However, unlike control modules, which seek rewards that calm (reduce arousal) with comfort and safety, active modal strategies are motivated to discover and produce activity that results in better-than-expected outcomes (surprise). Passive modal strategies operate in close conformity with Gray's behavioral inhibition system (BIS), showing a heightened sensitivity for startle, and signals of loss and risk (punishment).

Control modules, operating under the combined influence of active and passive adaptive modal strategies, gradually become highly refined and reliable but thereby risk losing the ability to produce prediction error and reward. Although valuable for purposes of culture building and survival, highly refined control modules are of little use for producing the excitement and surprise evoked by positive prediction error. By necessity, prediction error cannot be determined in advance; however, active modal strategies can incorporate control-module variations and novel actions to improve the likelihood of producing such error. Such modular variations and novel actions are referred to as *projects and ventures*. Ventures are distinguished from projects by the presence of an increased element of risk and potential for producing reward. As the result of the mutual and complementary influences of active and passive modal strategies, projects and ventures are gradually refined and fitted into the culture of modules, routines, and patterns of established behavior or they are extinguished. Consequently, it is not sufficient for a project merely to produce surprise in association with novelty (diverter), but the surprise must occur within a cultural context of established prediction-control expectancies; that is, it must be relevant to the existing culture and contribute to the process of adaptive optimization.

Dynamic Modal Relations, Affection, Play, and Bonding

Cynopraxic training theory postulates that prediction discrepancies between what a dog expects to occur and what in fact occurs while engaged in some purposive social activity result in emotional changes or establishing operations calibrated to optimize adaptive adjustments to the error. As such, social emotions are dependent on the formation of interactive prediction-control expectancies and interactive exchanges that result in outcomes that to some favorable or unfavorable extent mismatch or deviate from those expectations. Social exchanges that result in reciprocal emotional changes are referred to as *transactions*. Favorable transactions mediate mutual adaptations conducive to a polity of integrated social relations or, in the case of unfavorable transactions, exchanges result in mutual reactivity, antagonism, and social disintegration. For example, highly predictable and orderly social

exchanges tend to produce formal relations, roles, and rule-based rituals of limited emotional and behavioral variability that are integrated into a rigid utilitarian hierarchy. Although a utilitarian polity of rigid dominant-subordinate relations and expectations can be productive in the context of a culture of well-established modules, routines, and patterns of interaction organized to perform some specific function, such hierarchical relations are relatively inflexible to change and lack the capacity to produce transactions conducive to positive prediction error and reward in support of affectionate bonding. Social transactions that are conducive to familial or guardian relations and roles are more flexible and mediate attachment, dependency, and feelings of comfort and safety (security). However, familial relations and roles tend to become progressively formal, rule based, and problematic with respect to emergent interactive conflict and tensions involving the ownership and control of group resources and sources of reward. The interactive conflict associated with familial hierarchies results in dispersal or the production of an ISS in response to punitive transactions.

The cynopraxic polity is formed in the context of resolving interactive conflict developing in association with conflictive familial relations and roles. Typically, interactive conflicts form around antagonistic control incentives, whereby the dog's interest in obtaining some reward object or activity is at variance with the owner's efforts to establish or maintain control over the dog's seeking impulses. Such situations become conflictive as the result of punitive efforts to block or suppress the dog's reward-seeking activity, but without subsequently leading the dog to obtain sought-after gratification via a reward deferment or delay of gratification (e.g., making the dog wait) or prompting a more acceptable substitute behavior (submissive ritual) and rewarding it with an alternative object or activity that provides a similar or greater amount of reward value to the dog than the one being forbidden. The punishment of appetitive and social seeking activities performed in the absence of alternative sources of gratification appears to set the stage for the development of an ISS. Interactive conflict is gradually resolved by means of integrated compliance training (ICT), whereby forbidden activities and resources are systematically integrated as rewards for compliant behavior (see *Integrated Compliance Training*). In the process of resolving interactive conflict and tension by means of ICT, significant amounts of positive prediction error (rewarding surprise) are produced to mediate the expression of cooperative modal strategies. According to this view, competition is a necessary precondition and elemental aspect of all forms of social cooperation and happiness, that is, adaptive success. Without competition, there is no cooperation, without cooperation there is no happiness, and without happiness there is no joy. Competition is the foundation upon which a friendly relationship is built. As the result of ICT, interactive conflict is gradually resolved and replaced with interactive harmony and mutual appreciation.

With the emergence of interactive harmony, dynamic modal relations can be formed in the context of establishing affectionate and playful relations conducive to cynopraxic bonding. Dynamic modal relations consist of affectionate and playful give-and-take exchanges and creative social projects and ventures conducive to mutual reward (positive prediction error) and a joyful bond. Dynamic modal relations are liberated in the context of affectionate and playful transactions. Playful projects and ventures are an important source of variety and positive prediction error in support of friendly social relations, cooperation, and interactive harmony. Dynamic modal relations formed in association with play (reversing dominant-subordinate relations and role playing) mediate the transformation of competition into energetic, organized, and friendly cooperation. Play is an expression of freedom and represents a life symbol of adaptive success and harmonic social integration. Social play is possible only under the influence of a polity of mutually trusting relations. As such, play mediates social flexibility and cooperative-competitive dynamic modal relations and voluntary subordination strategies based on trust, mutual appreciation, interactive harmony, and joy.

Relations formed in association with affection and play cannot be forced, and they

remain free from the influence of coercion, providing a basis of interaction conducive to a VSS Insofar as affection and play are freely given, freely received, and freely reciprocated, dynamic modal relations facilitate the integration of a harmonic social bond. Dynamic modal relations are *practiced* while giving and receiving affection and while engaging in experimental role playing and the mutual expression of flexible ascendant and descendant role reversals. In contrast to dominant-subordinate relations, dynamic modal relations and roles are fluidly and playfully expressed, exchanged, and reversed, with little more objective in mind than to maintain and intensify the relationship and its capacity to support transactions conducive to heightened feelings of mutual appreciation and trust, that is, to enjoy each other. Dynamic modal interaction becomes progressively spontaneous and free, with social transactions taking on a quality of joyful anticipation arising from the mutual anticipation of positive prediction error, thereby enlivening the relationship mutual appreciation and joy.

C-type and M-type Affinity for the Flight-Fight System

A history of friendly and supportive interaction provides an affiliative buffer and physiological calming effect, whereby the shock of exceptions to the rule or the new is absorbed by a schema-consistent bias toward reward, even though the interaction might signify a momentary setback or loss (e.g., taking a bone) or threat (e.g., unexpectedly grabbing the dog) at the sensory-input level or uncertainty (e.g., meeting a visitor at the door). Well-socialized and competent dogs learn to perceive and interpret the significance of interaction in terms of spatial, temporal, social, and contextual schemata built up in association with safe and supportive interaction with family members and others. Organizing behavioral activity in accordance with flexible prediction-control expectancies offers enormous advantages, enabling the dog to prepare in advance for impending events and to optimize its adaptive efforts to predict and control significant social exchanges (see *Functional Significance of Social Signals*). The overall effect of such social interaction is the integration of relations conducive to a VSS and a trust-based bond.

However, social environments lacking order may prevent a dog from establishing a coherent system of prediction-control expectancies, thereby impeding its ability to adjust effectively. Social interaction that lacks adequate predictability and controllability may cause modal activity to become progressively perturbed and reactive. Without an orderly and coherent foundation of standard or normal expectancies, the dog is not only deprived of the calming effects (secure mood) of somatic reward and enhanced comfort and safety, it is also barred from advancing to an organization of learning and adaptation conducive to cortical reward (e.g., surprise), and freedom, that is, behavior liberated from reactive adjustments. According to this hypothesis, uncontrollable reward and punishment, that is, aversive or appetitive events occurring independently of the dog's initiative or ability to control them, gradually leads the dog to become increasingly dependent, insecure, and incompetent. Instead of depending on its own initiative and ability, the dog may rely on the owner's daily vagaries and whims to obtain gratification for its comfort and safety needs. Since a dependent dog's needs for attention, comfort, and safety inevitably exceed the owner's ability or willingness to gratify them, an inherent state of dissatisfaction develops between the owner and the dog as the result of such interaction. A dependent and reactive dog is rarely content or secure with what it gets (it is invariably too little or too late), an insecure attachment and resentment (submission with insecurity and anger) seem to present in common with such problematic relationships.

As the result of nurturance (affection and caregiving) and punishment provided on a habitually noncontingent basis, the locus of control over significant attractive and aversive events may be externalized, that is, placed outside of a dog's voluntary initiative. For such dogs, the acquisition of comfort and safety may be integrated and experienced as something that happens to them, rather than perceived as something that they control and produce for themselves. Instead of learning to control such events by proactive means, they

simply learn to receive or react to them. Just as the loss of control over aversive events is conducive to the debilitating effects of learned helplessness, the loss of control over appetitive ones can exert a similarly paralyzing effect on a dog's ability to adapt (Sonoda et al., 1991), perhaps a condition better referred to as *learned hopelessness* in the case of uncontrollable appetitive events. A persistent loss of control over significant events, whether appetitive or aversive, may render a dog progressively incompetent, emotionally undifferentiated, and straddled by a pervasive neediness (hopeless) and insecurity (helpless). Since what an overly dependent dog gets is provided or avoided on a relatively noncontingent and uncontrollable basis, it fails to obtain the confidence building and relaxing benefits of somatic (calming) and cortical (elating) reward. The inevitable uncertainty and insufficiency of such an arrangement may predictably lead to significant frustration and anxiety, perhaps helping to explain the increased irritability, intolerance, and resentment frequently shown by such dogs. Overly dependent and reactive dogs may possess a very impoverished set of control expectancies, operating primarily under a narrow range of motivations and behaviors dedicated to maintaining the dependent relationship. Lacking the ability to control significant social, appetitive, and aversive events by proactive means, such dogs may show signs of heightened vigilance for opportunities or threats and a boosted readiness to act impulsively, becoming increasingly insecure, needy, demanding, and obtrusive—characteristics of an ISS (see *Involuntary Subordination and Canine Domestic Aggression*).

In contrast to the rich and complex social schemata and organized scripting of well-adjusted and obedient dogs, overly dependent and reactive dogs appear to operate under a limited set of reactive expectancies biased with anticipatory anxiety, frustration, and a readiness to flee or confront benign threats and challenges with impulsive and disproportionate aggression or fear. Overly dependent and reactive dogs appear to be unable to integrate a trusting bond. Such dogs may become progressively insecure and intolerant of interference while engaged in comfort and safety-promoting activities (e.g., resting and eating). They may resent and react to benign handling and changes in routine or habit. Such dogs appear to exhibit a negative cognitive bias and a selective attention for signals of punishment (loss and risk) and show a reactive affinity for FFS adjustments via anxiety (fear) and frustration (anger). Instead of responding to aversive or appetitive events in a measured and calibrated way, socially incompetent and reactive dogs may evidence varying degrees of impulsivity and a reactive coping style. Psychological stressors associated with adverse social interaction, especially uncontrollable or inescapable compulsion or punishment, may cause anxiety and frustration to shift motivationally in the direction of fear and anger, becoming progressively prominent, generalized, and reactive. The persistent frustration associated with a loss of control over significant events may result in an increasing readiness for social confrontation and aggression via an affinity with the anger-arousing branch of the FFS. The increased anxious vigilance and frustrative readiness associated with the reactive coping style are hypothesized to result in chronic stress and an increased risk of developing serious adjustment problems involving impulsive adjustments, including aggression.

As the result of individual differences, prenatal or postnatal stress, abusive or neglectful rearing practices, excessive interactive conflict and disorder, and chronic stress, pathways mediating anxiety and frustration may become sensitized and lose their capacity to adaptively regulate emotional arousal. These changes result in a spectrum of predispositions, behavioral threshold modifications, and adjustment characteristics consistent with Pavlov's choleric (c type) and the melancholic (m type) typology. The vast majority of dogs exhibiting reactive coping styles show a blend of behavioral characteristics evidencing both C and M elements or showing only moderate signs of BAS and BIS dysregulation and stress-related disorder. The c-type dog is highly motivated and prone to frustration-related reactivity and aggression (frustration intolerant). C-type dogs exhibit a reduced capacity for delay of gratification and passive-avoidance learning.

M-type dogs, on the other hand, may become progressively withdrawn, socially avoidant, and fearful, often showing a lack of interest in appetitive and social rewards, and consequently may be very difficult to train with rewards. M types show an increased capacity for delay of gratification and passive-avoidance learning, but may show striking deficiencies with respect to adjustments requiring active-avoidance learning. Although both c- and m-type dogs are reactive to punishment, c types show a heightened sensitivity or *readiness* to respond actively and offensively to threats of loss and frustration, evidencing a high degree of fearlessness, whereas m types show a heightened sensitivity or *vigilance* and a tendency to respond passively and defensively to threats of harm and anxiety, evidencing a high degree of fearfulness. Both c- and m-type dogs are oriented to signals of punishments (loss of gratification or threats of harm), resulting in global learning deficits, emotional disturbances, and adverse mood changes, in association with an inability to produce and sustain a state of comfort and safety (somatic rewards) as well as a failure to produce positive prediction error and surprise (cortical reward) via integrated active and passive modal activity.

C-type and m-type dogs tend to orient and engage the environment with a reactive coping style, vigilantly and selectively scanning for signals of punishment and exhibiting a behavioral affinity for the FFS. Depending on predisposing behavioral thresholds, c-type and m-type dogs tend to differentiate with increasing aggressive irritability (c type), fearful anxiousness (m type), or both, as in the case of panic-related aggression and separation distress. Also, c-type and m-type dogs are prone to show reactive aggression and escape behavior in response to conditioned triggers, making them vulnerable to CDA and phobias, respectively. The reactive dog's preoccupation with and scanning for signals of punishment is problematic and the source of escalating anxiety, fearfulness, and relative immunity to normal counterconditioning efforts—procedures requiring a sensitivity and responsiveness toward signals of reward and a capacity to form functional prediction-control expectancies. Also, many of these m-type dogs show pronounced psychogenic anorexia that is refractory to food deprivation or the provision of highly appetizing food rewards. Finally, both c-type and m-type dogs show deficiencies with respect to their ability to initiate and sustain social play. To the extent that moderately unstable c-type and m-type dogs can be encouraged to play and to accept food and petting, a stabilization effect may be mobilized toward more adaptive coping styles.

In contrast to the reactive coping styles of c and m types, sanguine (s type) and phlegmatic (p type) dogs show distinctive adaptive coping styles. S types tend toward an active modal orientation (e.g., seeking and risk taking) with a BAS affinity, whereas m types tend toward a passive modal orientation (e.g., hesitating and risk avoidant), showing an adaptive response to anxiety and frustration. S types exhibit a selective attention and preference for signals of reward and playful modal activity. On the other hand, p types show a selective attention and preference for signals of successful avoidance, with a hesitation-sensitized affinity for the BIS (see Gray, 1990). S-type and p-type dogs may show defensive aggression and fear (attack and escape), but almost always only in response to unconditioned aversive stimuli that are otherwise uncontrollable. The vast majority of dogs incorporate a balance of s-type and p-type characteristics acquired in the process of coping and adjusting adaptively.

Filial and Sibling Dominance-Submission Relations

Dominance, leadership, and nurturing relations analogous to those exhibited by the wolf family/group appear to develop between people and dogs. The establishment of dominant-subordinate relations naturally emerges in the context of a puppy's relationship with the mother and by extension the dog owner. Puppies do not need to be made submissive but come readymade as obligate subordinates and, to the extent that they beg for nurturance (e.g., affection, food, and play), they are submissive. In contrast, the owner may fail to become a competent leader or misunderstand

the significance of the puppy's persistent and intrusive active-submission behavior, perhaps interpreting it as a defiant threat to the household's social order. Instead of embracing the puppy's enthusiasm and keen motivation and using them to shape more appropriate behavior via contingencies of reward or rules, the owner may attempt to punish them or mechanically suppress them with excessive crate confinement. As a result, the incompetent leader and the puppy may gradually become wedded to a futile ritual of confusion and conflict involving convergent but antagonistic control incentives and relations. This general scenario of involuntary subordination is an all-too-common perversion of social dominance, in which submission and subordination occur in association with interactive conflict and stress. Instead of mediating friendly and mutually calming relations in association with adaptive coping styles, the owner and the puppy may become locked into a adversarial contest of wills.

Alternatively, owners may neglect to assert competent control and limit-setting actions. As a result, the puppy may become progressively intrusive and demanding in ways consistent with sibling competitive interactions, including playful sparring, harassment, and obtrusive interference. Family members who neglect to establish competent social limits may become the object of intrusive excesses (see *Competitive Social Excesses* in Chapter 6). To build a successful relationship and bond with the dog, the trainer must be both tolerant and able to set appropriate social limits constructively, as Schenkel (1967) nicely describes in the case of wolf social behavior:

> If the superior is tolerant but fails to display his superiority, the inferior may behave obtrusively. In case the superior is not tolerant, i.e., threatens or even attacks the inferior, the latter tries to escape and defend himself and shows signs of social stress … We may conclude that submission is a contribution by the inferior to harmonic social integration on the basis of social hierarchical differentiation. It does not elicit a stereotyped automatic response. Integration asks for a contribution by the superior also, that is, tolerance. The superior's contribution may even exceed submission in its competence to shape the social contact or relation. (325)

Involuntary Subordination and Canine Domestic Aggression

Whereas the differentiation of social relations and roles associated with filial submission appears to be based on obligate subordination (social polarity, active submission, and begging), the roles and relations associated with sibling competition involve a variable history of previous competitive successes and dominance-related behavior. Sibling competition appears to be organized in accordance with prediction-control expectancies and emotional establishing operations, giving rise to emergent adaptive (s type and p type) and reactive (c type and m type) strategies for coping with social conflict and tension, including (1) a VSS (affectionate submission, playfulness, confidence, flexibility, friendly, and appeasing) and (2) an ISS (obtrusive and interfering, adversarial and rigid, and reactive anger or fear).

The involuntary subordination theory of CDA suggests that dogs are socialized and trained from an early age to accept voluntary or involuntary subordinate roles with respect to family members who are conducive to an adaptive coping style (compromise and cooperation) or reactive coping style (conflict and flight-fight reactivity) that persists throughout a dog's life cycle. As a result of competent socialization, limit setting, and reward-based training (parenting style), a generally affectionate and submissive VSS is integrated into friendly and cooperative relations with family members. However, as the result of incompetent socialization and force-based training (dominating style), a dog may adopt an ISS, showing oppositional, conflictive, and reactive flight-fight behavior toward family members. Such dogs and households may fail to integrate relations conducive to the formation of a trusting bond. The ISS expresses itself in a broad spectrum of problem behaviors occurring within the household. Over the course of a dog's development, competitive tensions and reactive triggers evoking threat or overt

aggression may develop around contested resources and privileges. As dogs reach maturity, interactive conflict and the potential for overt aggression may assume a more ominous significance, with dogs sometimes delivering serious attacks against the interference of family members (see *Filial and Sibling Dominance-Submission Relations*).

Whether aggression emerges or not in association with an ISS depends on biogenetic and ontogenetic influences, including the dog's relative excitability, behavioral thresholds controlling the activation of the FFS, and allostatic (stress) load. Allostatic load refers to the wider implications of stress, including biogenetic risk factors, early experience, lifestyle (nutrition, exercise, and play) and other quality-of-life influences, quality of social relations, and perceived control over stressors (McEwen, 2000). Too much or too little stress is problematic and potentially harmful. Dogs exposed to adverse prenatal or postnatal stress, abuse or neglect, or other sources of significant early stress may be particularly vulnerable to the disorganizing effects of psychological stress. Dogs showing heightened excitability with low anger/aggression (fight) thresholds (c type) tend toward offensive and impulsive aggression, whereas dogs showing a low fear/escape (flight) threshold combined with a medium-anger/aggression threshold (m type) are prone to show defensive and avoidance-related aggression. Excitable dogs showing low fear/escape and low anger/aggression thresholds are prone to conflict-related or panic-related aggression. Cynopraxic socialization and training conducive to a VSS exerts a protective influence against the development of household behavior problems by promoting a flirt-and-forbear coping style and consolidating an antistress, antifear, and antiaggression system, thereby offsetting adverse biogenetic and ontogenetic influences (see *Phylogenesis, Polymorphism, and Coping Styles* in Chapter 6).

Submission is mediated by establishing rights of ownership and setting limits around resources evoking seeking behavior. The valued resource or activity is then transformed into a reward by providing access to it in accordance with a rule and a submissive ritual (e.g., sit-stay), a change necessitating compromise and delay of gratification. The object of appetitive seeking is subsequently provided to the dog in exchange for cooperative behaviors in the context of leader-follower activities incompatible with intrusions upon the social limit. Positive prediction error (surprise) occurring in association with the gratification of ensuing leader-follower activities promotes the consolidation of a VSS and the acquisition of interactive modules, routines, and patterns of behavior conducive to the resolution of interactive conflict and tensions. The vast majority of dogs exhibit a balanced admixture of emergent dominant-subordinate characteristics enabling them to respond adaptively to socially competitive situations. Social competition and cooperation are intimately linked, and the dog appears to be biogenetically engineered to respond to competitive situations by expressing cooperative adjustments (VSS), if only the human companion is competent and able to confidently take the lead. Cooperative activity appears to depend on a structure of hierarchical relations emerging in association with competitive transactions and play. As a result, adaptive coping styles develop to promote affectionate submission and tolerance and mutual reliance and appreciation (tend and befriend) (see *Adaptive Coping Styles: Play, Flirt, Forbear, and Nip* in Chapter 6). Under the influence of adaptive coping styles, competitive social behavior is gradually differentiated into a complex set of cooperative and friendly dynamic modal relations, roles, and mutual expectations conducive to interactive harmony and trust.

SOCIAL DOMINANCE: DISPOSITIONAL CAUSE OR ATTRIBUTIONAL ERROR

The social dominance hypothesis is frequently appealed to in one form or another to explain CDA. Although the dominance model has value for understanding certain types and aspects of domestic aggression in dogs, the hypothesis can also be used to justify faulty interpretations and misunderstandings, based on misleading linkages between dog aggression and social dominance (see *Concept of Social Dominance* in Volume 1, Chapter 8). As a result of bias and misinformation,

attributing dispositional causes such as dominance to explain aggressive behavior is risky and prone to anthropomorphic error and the elaboration of explanatory fictions. The issues involved are complicated but deserve focused attention in advance of considering treatment protocols and procedures. Avoiding explanatory fictions is significant with respect to treatment programs because such errors adversely affect the way in which aggression problems are framed and approached, thereby influencing the selection of procedures used to address the problem. Historically, since dominance was viewed as something achieved by means of force and threats (Most, 1910/1955), the dominance hypothesis was and continues to be used in some quarters to justify inappropriate physical punishment and brutalization for the control of aggression problems. In addition to justifying inhumane methods, protocols and procedures that are based on phantom causes are doomed to produce chimerical cures. Social dominance is a significant and valid construct, but it requires careful definition and delimitation for practical use in the context of training and behavior therapy.

Dependent, Independent, and Intervening Variables

Observing and measuring behavioral changes as they occur in response to the presentation of highly controlled events or conditions is central to the experimental study of behavior. Most laboratory research involving animal behavior and learning involves a methodology in which antecedent and consequent events are rigorously defined and controlled. Behavior occurring under the influence of arranged antecedent and consequent events or conditions is referred to as *conditioned behavior*. The various controlled conditions or antecedent or consequent events are referred to as *independent variables*, whereas the observed changes in behavior that occur dependently in association with their presentation or omission are referred to as *dependent variables*. Independent variables are related to dependent variables as causes are related to effects. Many scientific theories also postulate another set of variables that, although not directly observable, are believed by inference to mediate or intervene between causes and effects. For example, in mechanical physics, the ability of one object to displace another is understood in terms of a variety of postulated intervening variables, such as gravity, mass, inertia, and momentum. No one has ever seen gravity, but the existence of gravity is inferred from the observable movements of objects and the effects they produce on the motion of other objects.

Intervening variables are often used to help explain how independent and dependent variables are related to one another, thereby rendering the relationship between them more predictable and controllable. For example, although the contingent presentation of food (independent variable) *can* increase the frequency of some target response (dependent variable), the presentation of food does not necessarily result in reinforcement; that is, the presentation of food does not necessary strengthen or increase the rate of responding. In order for food to function as reliable reinforcer, at minimum, a dog must be motivated to seek and eat food when it is presented; that is, the dog must be hungry. According to this interpretation, hunger is inferred as the intervening condition making the presentation of food more likely to result in reinforcement. Radical behaviorists reject intervening variables as being unnecessary for studying behavior. Instead of postulating hunger as an intervening variable, these researchers collect information about the animal's weight or the length of time that it has gone without eating—deprivation period. Theoretically, with the accumulation of data concerning the effects of deprivation on reinforcement, and holding all other independent variables constant, one would be able roughly to predict the probable size of the effect that reinforcement will have on the frequency of the target response based on the number of hours that the animal has been deprived of food.

Explanatory Fictions

Intervening variables such as hunger, thirst, and sleepiness are relatively harmless, providing a reasonable and useful, if not entirely reliable or scientifically framed, simplification

for understanding the motivations underlying ordinary behavior. However, the use of intervening variables to understand the causes of complex social behavior is subject to several potential sources of error, including the promulgation of explanatory fictions. Explanatory fictions occur when an intervening variable is inferred as a cause mediating some behavioral effect where in fact no such causal relationship exists. The assignment of attitudinal attributions (e.g., "the dog is stubborn"), emergent dispositional attributes (e.g., attachment and social dominance), and appeal to emotional states as mediating causes are particularly prone to error and fictionalizing. Despite the risk of error, appeal to dispositional intervening variables is common in applied settings (e.g., boredom, conflict, stress, anxiety, frustration, or dominance). Since the identification and interpretation of dispositional causes are often an important aspect of behavioral diagnosis and treatment decisions, it is of utmost importance that such causes be carefully delineated; otherwise, treatment efforts may be inefficient or ineffective. In some cases, faulty dispositional inferences and explanatory fictions can be extremely harmful and represent significant obstacles to effective treatment. For example, owners commonly interpret their dogs' aggressive behavior as stemming from defiant belligerence. Responding under the influence of such an explanatory fiction, the owner may resort to severe punishment, thereby damaging their relationship with the dog and probably making the problem far worse and more difficult to resolve.

Fundamental Attributional Error

Explanatory fictions incorporating dispositional accounts are prone to develop when causal explanations require the consideration of events not immediately present or indicated by situational evidence. Dispositional causes are inferred from the situation, whereas the actual formative causes may not be present in the situation (e.g., adverse or inadequate socialization), but may be far removed from it and unavailable for consideration. Behavior observers tend to underestimate the causal significance of situational factors while overestimating the importance of dispositional factors in the control of behavior—a tendency known as the fundamental attributional error (Ross and Nisbett, 1991). The tendency to emphasize attitudinal or disposition factors (dispositionism) over situational ones appears to be most common in cases where immediate and remote causes (dependent variables) are ambiguous or unknown. In addition to being prone to error and misinterpretation, the assignment of attitudinal and dispositional causes tends to preclude or obscure the consideration of possibly more influential immediate and remote causes affecting a dog's behavior. In this regard, people tend to attribute situational causes to their own actions, while tending to attribute dispositional causes to the behavior of others, probably including other owners and their dogs (actor-observer discrepancy). For example, failing to meet a deadline, a person might explain their shortcoming by appealing to something that unexpectedly came up, whereas, if someone else fails to meet a deadline, there is a strong tendency for an observer to explain it by dispositional causes, such as laziness or the person is not interested in the project, rather than looking for proximal or remote situational causes. Finally, a significant motivation for attributing dispositional mediating causes to behavior is to provide a perception of enhanced predictability and control over it; even if in actuality the causes are fictitious and the treatment a placebo, nonetheless, one may feel more in control!

Dispositional versus Situational Causes

In comparison to the way in which the behavior of children is interpreted, dogs enjoy a significant *positive bias* in the direction of leniency and more favorable attributions (Rajecki et al., 1999). Attributional processes appear to be influenced by the sort of behavior involved. Observers tend to excuse dogs from antisocial behavior while crediting them with responsibility for prosocial behavior. Interestingly, whereas prosocial behavior is commonly attributed to internal and controllable dispositional causes, aggres-

sive behavior is more likely to be attributed to external situational causes not under the dog's control.

Barring obvious limitations and provisos, dispositional attributions are not without value as a sort of predictive shorthand. In fact, emergent dispositional attributions resulting from careful observation are often highly predictive of future behavior. For example, a dog that has repeatedly submitted to owner limit-setting imperatives may rightly be called subordinate and submissive to human control, whereas a dog that consistently resists or defies owner control efforts may be rightly referred to as being competitive or oppositional. To what extent, though, are such post hoc descriptions consistent with the actual causes underlying the submissive and the opposition behavior; that is, to what extent is a dog's obedience to command attributable to submissiveness or disobedience attributable to the influence social dominance? In fact, dogs submit or compete as the result of a variety of causes. A pattern of apparent competition and unwillingness to submit may be due to a dog's temporary inability to exert inhibitory control over its behavior, despite its best efforts to submit to owner control efforts. In such cases, the dog's failure to obey and actively defer is not due to a disposition to compete and defy the owner's authority, but rather may be interpreted as the result of a temporary loss of inhibitory impulse control. Dispositional causes related to impulse-control deficits probably play a significant role in the competitive excesses of puppies. Impulse-control abilities in young puppies are developmentally limited, with dogs only gradually acquiring the neurobiological capacity to exert impulse control in a refined and reliable way. In the case of young dogs, impulse and action are tightly wedded. Efforts to suppress actions may serve only to potentiate and frustrate underlying impulses. The regulation of impulses is probably localized in prefrontal cortex, an area of the developing brain that may not be fully formed until late in the first year with the emergence of enhanced cognitive abilities (Gagnon and Dore, 1994) (see *Learning and Trainability* in Volume 1, Chapter 2).

Dispositional attributions not only affect the diagnosis of behavior problems, they also determine the likely course of treatment. Remembering that dispositional attributions are made in order to enhance control over a dog's behavior, it is logical that behavior believed to stem from defiant competitive motivations would be treated with procedures aimed at increasing a dog's submission to authority. Unfortunately, a dog's degree of submissiveness may be entirely irrelevant with respect to the actual causes underlying its inability to obey owner directives. Whereas physical restraint and punishment may enhance submission in cases where "defiance" is identified as the mediating dispositional cause of competitive behavior, such treatment would be entirely inappropriate in the case of impulsive behavior stemming from hyperactivity, attention or impulse deficits, or immaturity. Unfortunately, such distinctions are not consistently made, and dog behavior problems are often lumped together under the misleading rubric of dispositional causes, such as competitiveness or attention seeking, rather than ontogenetic or situational causes that may be more illuminating and useful. Dogs often seek attention with reference to objectives and needs other than the acquisition of social attention itself (e.g., they seek the owner's attention because they want food or because they want to go outside and so forth); likewise, dogs often compete and oppose owner directives as the result of situational incentives competing for the dog's interest—not as the result of a defiant disposition to resist owner control efforts. Outside of play, where competition may occur solely for the sake of interactive fun, competition is usually limited to situations in which the owner's control directives either thwart or interfere with a dog's enjoyment of some activity, object, place, or other valued resource, including the owner's presence. Other common dispositional causes attributed to competitive behavior may be self-serving to the extent that they are invoked to rationalize abusive training practices. For example, a dog's momentary unwillingness to obey an obedience command may be mistakenly interpreted as stemming from sullen defiance, whereas, in fact, the

dog's disobedience and appearance of sullenness may be due to other causes (e.g., arthritic pain or emunctory distress), giving the appearance of resistance and unwillingness to obey. Without knowing the true causes of disobedience, the trainer may feel justified in using harsh compulsory measures to force the dog to perform.

Anthropomorphic Errors

Much harm is done to dogs as the result of attributing anthropomorphic dispositions and motivations to canine behavior. In general, cynopraxic counselors should resist temptations to unnecessarily attribute complex psychological causes to dog behavior in adherence to C. Lloyd Morgan's famous law of parsimony: "In no case may we interpret an action as the outcome of the exercise of a higher psychical faculty, if it can be interpreted as the outcome of the exercise of one which stands lower in the psychological scale" (Morgan, 1894:53). Nowhere is such restraint and self-discipline more necessary than when assessing the situational and dispositional causes underlying aggressive behavior, especially aggression directed toward family members.

Although most dogs are benignly subordinate and submissive toward their owners, some do appear to actively assert limits on their owner's behavior by way of threats and limited attack, suggesting that social dominance may play a dispositional role in the etiology of some forms of CDA. Domestic aggressors may threaten or bite if family members intrude upon a forbidden location, disturb them while resting or sleeping, threaten them with discipline, attempt to take something away from them, attempt to restrain them, and so forth. Of course, most dogs readily give up control over sleeping areas and chew objects, accept handling of all kinds, including punitive treatment, without ever resorting to threat displays or biting. Further, the environmental conditions are relatively constant between dogs that bite and those that do not bite. Why, then, does one dog passively submit while another one threatens or bites? According to the social dominance theory, the primary cause of aggression in such situations is related to social status. The household aggressor either bites in response to a violation of its status or attacks with the goal of improving its social rank. This general theory is problematic on a number of grounds that have been explored in some detail in Volume 2. There are many potential causes standing lower than the defense or enhancement of status on Morgan's psychological scale to explain such behavior that should be systematically excluded when performing a behavioral assessment and diagnosis.

Dominance as a dispositional cause can be easily confused with other remote (e.g., ontogenetic), situational, and dispositional causes (e.g., irritability and frustration) that may be more directly relevant to behavior-therapy efforts. Although competitive conflicts may escalate into aggression, aggression is not necessarily the result of motivations associated with dominance, particularly not in sense of status and rank. For example, although dogs may become aggressively aroused when they are pulled away from sleeping or resting areas, the incentive to threaten or bite at such times may be borne out of a momentary autoprotective incentive to expediently control irritating or frustrating interference. Such domestic aggressors are not necessarily challenging family members for rank, but are simply responding reactively and incompetently to the handling and the momentary loss of comfort and safety. Dogs of this sort may lack the socialization and training necessary for them to respond in a more socially acceptable and cooperative way to intrusive and provocative handling. However, as the result of repeated offensive threats toward the owner, the dog may gradually assume a dominant relation toward the owner. This sort of CDA is most likely to result in ritualized threats and inhibited punitive biting, not severe and uninhibited bites that are commonly attributed to dominance.

Dogs that deliver hard and uninhibited bites often do so under the influence of varying degrees of panic and an apparent loss of impulse control—the antithesis of competent social dominance. The attacks of such dogs are often out of character, highly exaggerated, and disproportionate to the provoking stimu-

lus. Such aggression frequently occurs under the influence of circumstances similar to that just described, but the attacks seem to differ with respect to the level of emotional arousal, the degree of competency and control over the action, and their severity. Panic-related aggression appears to occur in association with heightened autonomic arousal, behavioral rigidity, and a conflux of coactive emotional influences (e.g., anger, irritability, frustration, and fear) resulting in the catastrophic dysregulation of aggressive impulse. When punished, such dogs do not back down or retreat, giving them an appearance of fearlessness. Instead of submitting or fleeing when punished, panic aggressors tend to escalate their attacks rapidly under the excitatory influence of fear. In contrast to the impulsive character of panic-related attacks, competent control-related aggression is more likely to occur in accordance with prediction-control expectancies and a cost-benefit assessment, such that aggressive challenges or threats are rapidly abandoned if they prove too costly when they fail or offer little promise of benefit when they succeed.

Social Dominance as a Dispositional Cause of Aggression

Erringly identifying the causes of aggression as stemming from a dominance conflict may result in the initiation of training efforts designed to enhance owner dominance and control—efforts that may or may not be relevant to the actual causes underlying the problem. In other cases, the attribution of dominance may result in the use of highly intrusive and aversive procedures believed to alter canine social status.

The attribution of social dominance in the sense of rank or status as a primary cause of CDA is flawed and inconsistent with Morgan's law of parsimony. Most instances of CDA can be interpreted in terms of functional causes, including conditioned expectancies, adverse emotional influences, and conflict. Consequently, the term *control related* appears to more closely approximate and capture the intent and significance of such aggressive behavior. In any case, the term *dominance* is primarily used here in the sense of limit-setting actions, that contribute to social competency and foster the integration of a submissive bond. Domestic aggression most often reflects the influence of social confusion and a failure of the owner and the dog to interact in an organized and competent way with each other. As the result of past competitive successes involving aggression, attacks against family members may become more frequent and severe under the influence of conditioned aversive arousal (anxiety, frustration, irritability, or anger), stress-related disturbances, and the presence of inadequate social coping and communication skills.

Adverse Environmental and Emotional Influences and Canine Domestic Aggression

Most CDA currently attributed to dominance lacks a confident quality, making the diagnostic attribution of *dominance related* highly suspect in such cases (Guy et al., 2001). Such aggression appears to be more anxious and reactive than proactive and fearless. Impulsive aggression occurring under the influence of conflict might best be described as *autoprotective*. Instead of speculating and attributing excessive causal significance to rank and household dominance hierarchies, the causes of most CDA can be better understood and described in terms of distal polymorphic variances (individual differences) affecting excitability, fear and anger thresholds, and sociability; ontogenetic influences such as prenatal and postnatal stress, exposure to early adversity (abuse or neglect), socialization and habituation deficits, and toxic expectancies; the presence or absence of protective social nurturance and training; and proximal provoking situations and social triggers, reactive coping styles and ISSs, diminished capacity to regulate emotion and impulse, coactive establishing operations (e.g., anger, fear, excitability, irritability, frustration, and conflict), and allostatic load. Although threat displays can advertise relative social rank and status, these social signals can also reflect underlying coactive emotional and motivational states and a heightened readiness to act in particular ways to control a provocative situation (Figure 7.1), inde-

pendently of standing dominant-subordinate relations. Aggression in association with owner control efforts typically involves varying degrees of elicited irritability, frustration, anger, or fear. Aggression in such cases is often triggered by owner interference or disturbance, conflicting with appetitive-seeking and comfort-seeking activities (control incentives or *vectors*). Gradually, as the result of actual or anticipated threats or losses, a dog may become progressively vigilant and irritable when approached, thereby gradually lowering aggression thresholds in association with owner intrusion or interference (comfort/safety violations). For example, approaching a dog with a history of object guarding and aggression while it is in possession of a bone evokes varying amounts of conditioned anger or irritability, emotional changes established in association with a history of owner intrusion and interference. Dogs prone to react aggressively to social signals associated with discipline (e.g., loud voice, direct stare, or abrupt reaching or leaning over actions) and restraint may also be responding under the influence of varying degrees of anxiety, frustration, or anger stemming from past experiences associated with positive or negative punishment (see *Anxiety, Frustration, and Aggression* in Volume 2, Chapter 8). These two general sources of aggressive arousal are respectively referred to as loss of comfort and loss of safety. *Comfort loss* refers to interference or intrusion upon activities and sources of stimulation that the dog would wish maintain or intensify. *Safety loss* refers to interference or intrusion that involves a threat or presentation of events that the dog would prefer to escape or avoid. Provocative comfort loss or safety loss are the two primary ways in which control-related aggression develops. The traumatic loss of comfort or safety may be especially problematic in dogs having formed close attachments with their owners (loss of trust), in dogs that have not learned how to cope competently with loss, in dogs exposed to provocative comfort and safety loss on a relatively unpredictable or uncontrollable basis (conflict), and in dogs operating under the influence of toxic expectancies resulting from a history of traumatic or abusive handling.

In addition to social causes, biogenetic and developmental influences appear to predispose some dogs to develop aggression problems. Dogs with reactive and excitable temperaments appear to be more prone to exhibit CDA (Dodman et al., 1995; Borchelt, 1986; Podberscek and Serpell, 1997; Luescher, 2000; Guy et al., 2001b). The combination of low fear and anger thresholds, presenting with a high degree of excitability, may strongly predispose dogs for developing CDA problems in association with impulse dyscontrol and panic. Panic-related aggression occurs under the influence of adverse emotional stressors and provocative conditioned and unconditioned triggers that overstrain a dog's ability to control aggressive impulses. Such dogs may bite, not as the result of control-related incentives or dominance, but rather because of an inability to cope competently with a provocative situation. Panic-related aggression occurs as the result of a momentary loss of control over aggressive impulse. In contrast, control-related aggression refers to competent (proactive) and incompetent (reactive/impulsive) efforts organized to assert control over aversive or intrusive social events portending a loss of security (threat to comfort or safety). Control-related aggression includes both offensive (anger-related) and defensive (fear-related) forms occurring under the pressure of autoprotective incentives. Whereas panic-related aggression appears to stem from an internal loss of control over arousal states anticipating rage, control-related aggression is triggered by an external loss of control over significant social exchanges that can present with competent proactive forms aimed at promoting adaptive optimization by taking advantage of favorable cost-to-benefit ratios or incompetent forms (reactive and impulsive aggression) operating under the adverse influence of social ambivalence (anxiety) and irritability. In any case, most forms of competent and incompetent aggression are expressed as means to ends in subservience to autoprotective interests and concerns rather than the pursuit of social dominance and rank. Rather than attempting to alter the dog's perception of rank, training efforts should be dedicated to restoring or developing a social bond based on trust in situations

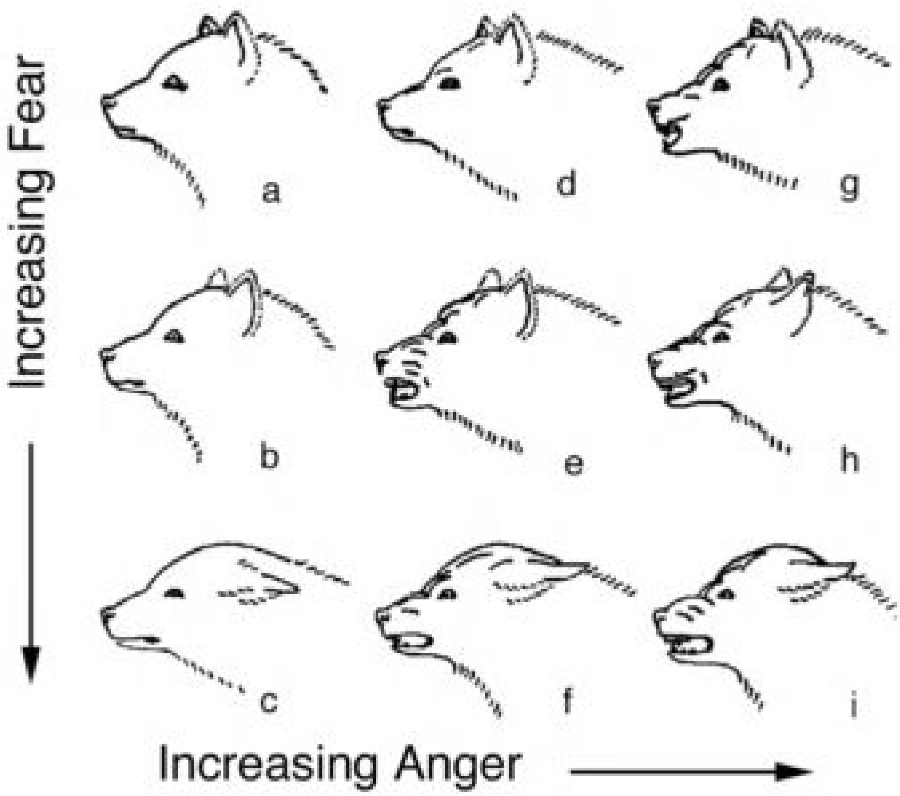

FIG. 7.1. Aggression occurs under the influence of varying admixtures of coactive emotional influences, such as anger and fear. These emotional states are reflected in a variety of postural and facial changes or signs that provide the receiver with information about the sender's probable course of future action, thereby enabling the receiver to better anticipate (predict) and adjust (control) to the impending situation. The facial expression in *drawing i* indicates signs of intense emotional arousal associated with the simultaneous provocation of high levels of fear and anger, a state of conflicted arousal that may overstrain executive impulse-control functions and result in explosive panic-related attacks in predisposed dogs. After Lorenz (1966).

that have provoked aggression in the past (Table 7.1).

Social Communication and the Regulation of Aggression

Functional Significance of Social Signals

Social communication provides a conduit of exchange and information about what affiliative partners are most likely to do in advance of them actually doing it (see *Communication and the Regulation of Social Behavior* in Volume 1, Chapter 10). In addition to signaling the sender's intent, communication serves to elicit preparatory emotional responses readying the receiver to act in certain ways. Depending on the sort of signal or display sent, the receiver is rendered more or less likely to greet, play, attack, submit, flee, and so forth; that is, the signal sets the occasion and elicits the emotional concomitants necessary for the emission of a certain class of behavior. As such, signals serve the dual function of discriminative stimuli and establishing

operations. As discriminative stimuli, social signals announce a moment when a particular set or class of behaviors is most likely to result in reinforcement. As establishing operations, social signals momentarily alter a dog's motivational readiness to behave in ways that are in keeping with the discriminative significance of the social signal presented (see *Antecedent Control: Establishing Operations and Discriminative Stimuli* in Volume 1, Chapter 7).

In an important sense, effective social communication serves to make the behavior of the sender and the receiver more predictable and controllable to each other; that is, the exchange of orderly social signals helps to promote more trustworthy and reliable interaction. Under the influence of an orderly exchange of social signals and mutual adjustments consistent with those signals, social behavior is gradually shaped and refined in the direction of enhanced interactive harmony, whereas, on the other hand, social signals that lack a consistent and orderly significance and presentation tend to impede the development of interactive harmony, resulting in increased levels of social conflict, anxiety, and frustration. As a result of interaction lacking consistency and orderliness, varying degrees of unease, distrust, tension, and potential for disturbance are inexorably introduced and maintained under the influence of deranged reinforcement contingencies and classical conditioning. In the context of aversive emotional arousal occurring in association with aggressive behavior, a lack of quality predictive information may lower aggression thresholds via anxiety, thereby increasing a dog's readiness to engage in disorganized defensive behavior.

Social signals involve both conditioned and unconditioned elements helping to make social interaction more predictable. Signals serving an establishing operation function are strongly influenced by feed-forward mechanisms that collect and appraise predictive information via the influence of classical conditioning (Domjan et al., 2000). Feed-forward information gives advance notice or warning of what is about to occur on the basis of what has occurred under similar circumstances in the past, thereby enhancing an animal's ability to control the impending occurrence by means of anticipatory adjustments that prepare it for appropriate action. Predictive social signals serve to make social interaction more effective and efficient, whereas unpredictive signals introduce escalating levels of anxiety and stress. Many common canine aggression problems appear to be under the control of Pavlovian feed-forward expectancies and instrumental contingencies of reinforcement. In addition, conditioned and unconditioned aversive and appetitive stimuli exert a direct excitatory or inhibitory effect on instrumental behavior, providing powerful means for modulating aggressive arousal and behavior (Dickinson and Pearce, 1977).

Dogs work to escape or avoid aversive social stimulation by means of behavioral adjustments that result in a reduction of the threat while simultaneously searching for safety from the danger. When the owner is

TABLE 7.1. Treatment of intra-familial aggression involves a multifaceted program consisting of at least eight elements

1. Exclude possible medical causes by veterinary examination and appropriate testing.
2. Obtain a thorough history and assess aggressive behavior.
3. Identify and reduce coactive emotional influences.
4. Systematically elevate pertinent aggression thresholds.
5. Improve the predictability and controllability of social interaction.
6. Promote interaction that is conducive to a restoration of trust between the family and dog.
7. Train the dog to respond more competently to situations involving appetitive loss or aversive threat.
8. Avoid unnecessary and provocative situations that may increase aggressive tensions or evoke actual attacks.

both the source of aversive stimulation as well as the dog's primary source of safety, a high degree of emotional conflict is likely to ensue with increasing levels of ambivalence, irritability, and intolerance. The traumatic disconfirmation of comfort and safety is hypothesized to evoke high levels of anger and fear, setting the emotional stage for reactive panic and aggression. Dogs that have formed close attachments with their owners may be energetically aroused by punishment, experiencing an unexpected discrepancy between a history of comfort and safety (security) conducive to trust and its rapid and traumatic loss. In cases where aversive stimulation is combined with an inescapable condition in which the owner ignores submissive signals and prevents the dog from getting away or otherwise controlling the punitive stimulation, biting to break free may be the dog's last resort. In the future when faced with situations portending similar treatment, the dog may preemptively threaten or bite the owner and flee to a hiding place in search of safety and protection. This is a very problematic state of affairs that frequently presents in close association with CDA problems. Such owners need to learn how to control their dogs more kindly and skillfully, while, on the other hand, such dogs need to learn how to respond more competently to social situations demanding obligatory subordination and cooperation. The dog's trust in the owner as a reliable source of comfort, safety, and consistency must also be restored—a change that is facilitated by cynopraxic training and therapy, attention and relaxation training, play, and a variety of predictable and controllable friendly interactions signifying comfort and safety to the dog. The cynopraxic process integrates owner relations with the dog consistent with a tend-and-befriend orientation, thereby activating a mutually beneficial antistress response, while mobilizing a VSS incompatible with flight-or-fight reactions.

Social Signals, Impulse Control, and Attention

Accurate prediction and control foster behavior that is appropriate to the circumstances in which it occurs—something that is commonly lacking in the case of CDA problems. Overstrain of attention and impulse-control faculties by adverse conflictive pressures originating from internal (e.g., emotional disturbances and stress) or external sources (e.g., unpredictable and uncontrollable events) may significantly impact upon a dog's ability to regulate its behavior, including aggressive impulses. Emotionally provocative stimulation occurring on a relatively frequent, unpredictable, and uncontrollable basis may be particularly problematic, inducing a high degree of conflict and stress. Dogs possessing unstable temperaments (choleric and melancholic types) may be more prone to exhibit various disorganized and maladaptive coping efforts when exposed to deranged environmental contingencies. Disturbances in attention and impulse control resulting from deficient prediction and control may also occur in situations where events are quite orderly but remain elusive to the dog because it has not yet learned how to apprehend them as such. Such difficulties may develop in association with inadequate socialization and training efforts. In such cases, remedial basic training may provide a therapeutic benefit by means of explicitly presenting significant events on a highly predictable and controllable basis—an influence conducive to enhanced social competence, confidence, and relaxation. Training activities also enhance both attention and impulse control, thereby improving human-dog communication and cooperation. Improved communication and cooperation promote interactive harmony and social trust between the dog and the owner, as well as helping to reduce physiological stress. Highly structured programs of ICT probably derive most of their aggression-reducing benefits from the enhancement of attention and impulse control rather then serving to alter the dog's social status. Finally, even though some dog-training authorities have overstated the importance of social dominance for regulating social interaction between people and dogs, the establishment of social order by limit-setting activities remains a necessary part of the training and socialization process.

Social Competition, Cooperation, Conflict, and Resentment

Social interaction integrating dominant and subordinate relations into cooperative activities by means of limit-setting actions, reward-based training, and play promotes emotional establishing operations and modal strategies conducive to social harmony. Under the ideal conditions of voluntary subordination, the filial/sibling subordinate defers to the leader/trainer's limit-setting actions with submission behavior. The leader/trainer nurtures active submission (affection and care seeking) with contingent rewards arranged to shape a cooperative pattern of interactive behavior. Essentially, cooperation is *gratified begging* organized to promote a friendly leader–follower bond.

Voluntary subordination is most likely to occur under conditions of minimal coercion, positive reinforcement, and play, whereby the subordinate's need for affectionate contact, nurturance, and protection are met by means of voluntary compliance to the trainer's leadership directives. The VSS is characterized by elevated mood (elation) associated with the success and safety obtained by cooperative compliance with a competent leader. Under the influence of adverse conditions in which subordination is coerced by means of punishment and maintained by threats, an ISS may develop in association with increased resentment and potential for CDA. The loss of effective social control and the ensuing conflict-related stress associated with ISS may result in depressed mood, increased irritability, and reduced tolerance for close contact and taction. The adverse effects of persistent involuntary subordination on emotional tone and mood have been theoretically implicated in the etiology of depressive illness in people (see Gardner, 1982; Price et al. 1994; Price and Gardner, 1995). In addition to social incompetence and intolerance, many offensive aggressors appear to be strongly affected by increased levels of anxiety and vigilance associated with involuntary subordination. Within the context of the family structure, these negative emotions may be selectively exhibited toward family members, depending on social considerations. During interaction with inferiors (e.g., children), the involuntary subordinate may exhibit heightened irritability and intolerance, whereas interaction with superiors (e.g., adults) may evoke vigilance and resentment. Interestingly, such dogs may show a particular fondness and tolerance toward children and adults incapacitated in various ways that prevent them from exerting a control threat to the dogs.

Species-typical Defensive and Offensive Aggression

Generally speaking, aggression is a risky activity that operates within limits of cost-benefit expectancies, weighing the benefits of success set against the potential costs of failure (see *Cognition and Aggression* in Volume 2, Chapter 6). Aggressors attack under a risk that the target victim might fight back and, in doing so, perhaps injure or kill the aggressor. The threat of punitive retaliation exerts a significant inhibitory effect over animal social aggression (Clutton-Brock and Parker, 1995). Punitive retaliation against violence is a natural and virtually universal response, the assumed effectiveness of which is reflected in its ancient origins and continuous worldwide practice as a preferred means to inhibit aggressive behavior. Despite these natural and cultural precedents for the use of punishment to control aggression, punishment in the case of CDA is complicated and generally avoided except in the case of overt attacks. Even in the case of overt attacks, though, punishment poses serious challenges and risks. Punishing an adult dog while it is in the act of an overt attack risks producing a more dangerous situation via vicious-circle effects (Melvin, 1971) (see *Reactive Types* in Chapter 5). If the punitive effort is insufficient to produce immediate inhibition, the escalating attack may continue until the punitive effort is discontinued, often at the moment at which the dog succeeds in breaking free by biting. As a result of ensuing negative reinforcement occurring at such times, threats or attacks may rapidly escalate and morph into a much more dangerous form in response to future owner control efforts. In addition, preemptive attacks may begin to occur in response to benign body

movements that resemble actions associated with the failed punitive effort (e.g., reaching or leaning over the dog). These adverse byproducts of punishment strongly militate against its use in the treatment of most forms of aggression.

Dogs respond to aversive events with a variety of species-typical defensive reactions (SSDRs), which provide rapid behavioral adjustments to threatening situations. SSDRs are highly stereotypic, phylogenetically significant, easily evoked, and rapidly learned as avoidance responses (see *Species-specific Defensive Reactions* in Volume 1, Chapter 8). In addition, dogs exhibit a variety of species-typical offensive reactions (STORs) that occur in response to socially provocative stimulation involving pain or frustration and the induction of anger. Antecedent social and contextual stimuli present at the time of provocative stimulation may be conditioned to control the preemptive expression of SSDRs and STORs. Not only is avoidance learning rapid, conditioning resulting in avoidance-related aggression is highly persistent and durable (see *A Cognitive Theory of Avoidance Learning* in Volume 1, Chapter 8; and *Conditioned Fear and Extinction* in Volume 2, Chapter 3). Whether a dog attacks or withdraws during punishment depends on biogenetic and developmental influences (temperament) affecting the functional thresholds controlling such behavior (see *Behavioral Thresholds and Aggression* in Volume 2, Chapter 8). Dogs possessing a low fear threshold and a high aggression threshold show a propensity to become fearful first, causing them to respond to aversive stimulation by various flight or freeze responses, such as running away or becoming rigid. At the other extreme, dogs with a low aggression threshold combined with a high fear threshold may rapidly transition into attack mode in response to minimal provocation.

Fearful dogs struggling to escape interactive punishment may eventually threaten or attack under the influence of escalating aversive arousal. Rather than flee or freeze in the future, these dogs may rapidly learn to threaten or bite preemptively in response to provocative social stimuli (see *Avoidance Learning and Aggression* in Volume 2, Chapter 6). Under the same interactive punishment, dogs exhibiting low aggression thresholds may eventually reach a fear threshold, causing them to freeze or flee or energizing their aggressive efforts under the excitatory influence of fear. Dogs exhibiting low behavioral thresholds for fear and aggression may be highly reactive and intolerant of provocative social stimulation. When exposed to physical punishment, such dogs may rapidly become enraged under the reciprocal excitatory influences of fear and anger on panic/rage circuits. Under the influence of sustained punishment, such dogs may become progressively violent (panic-related aggression). Dogs affected by elevated fear and aggression thresholds tend to exhibit tolerance for provocative social stimuli and enjoy a natural protection against the development of aggression problems.

Guy and colleagues (2001c) have questioned the relevance of dominance as an etiological factor in the development of CDA problems, arguing that aggression problems may be more closely related to the expression of temperament traits (e.g., excitability) and social anxiety/fear, perhaps more significantly so than social dominance. Such behavioral and emotional influences may be exacerbated by the use of punitive methods of control, perhaps further increasing the risk of aggression—practices that may be particularly problematic in the case of puppies showing low anger thresholds in combination with low or high fear thresholds. In such cases, physical punishment may trigger panic-related reactive aggression (low anger and low fear thresholds) or fearless attack (low anger/high fear thresholds) or cause aggressive behavior to rapidly escalate via avoidance learning and vicious-circle effects (Brown et al., 1964). Punishing reactive or fearless puppies may only serve to sensitize them to signals of punishment, however, instead of inhibiting the target behavior, punishment may actually increase aggression via vicious-circle effects, perhaps making the behavior more difficult to predict, control, and manage.

The use of interactive punishment for the control of aggression is problematic, but especially so when it is applied against threat displays (e.g., growling and snarling). The punishment of threat displays may cause dogs to

withhold threats and possibly to learn to bite without warning. Growling and other threat displays provide a trainer with valuable information about a dog's emotional state as well as give advance warnings of impending attacks. As a result, threat displays provide a layer of safety to family members and others coming into contact with the dog—protection that may be removed by punishment. In addition to potentially suppressing valuable warnings, punishing a threat display risks triggering an escalation of aggressive tensions, especially in the case of excitable dogs, perhaps triggering an overt attack and breaking the ALL IMPORTANT inhibition controlling the first hard bite. After the first bite, subsequent biting becomes much easier for dogs. The power of the native canine inhibition against biting can never be duplicated by any amount of training and, once it is broken, can never be fully restored.

Instead of punishing aggressive threats, it is far better to reduce the frequency of threatening behavior by modifying the social and environmental causes controlling it. Growling and other threats should be viewed as useful diagnostic signs and protective warnings that should be monitored and reduced by displacing aversive arousal with incompatible emotional and behavioral responses conducive to friendly cooperation and play. One option for managing trigger situations is to avoid them whenever possible and practical. For example, in the case of dogs whose threats or attacks occur only in the context of control-related incentives associated with physical punishment, owners can be encouraged not to use such methods of training. Physical punishment is something that owners can easily learn to live without after learning how to control and train their dogs by less intrusive and provocative means. However, in cases involving critical and unavoidable interaction with dogs (e.g., approaching, touching, handling, grooming, or restraining), various behavior-therapy and training procedures should be introduced to help manage and reduce the risk of future aggression while shaping various behavioral changes incompatible with aggression and promoting interaction that supports enhanced safety and trust. Finally, behavioral thresholds controlling fear and aggression are strongly influenced by experience. Puppies with low fear and low anger thresholds should be identified at an early age and provided with appropriate socialization and training. Although such puppies are at an increased risk of developing behavior problems associated with fear or aggression, owner counseling and early intervention appear to provide a protective influence.

LOSS OF SAFETY, DEPRESSION, PANIC, AND AGGRESSION

The formation of a close attachment between the owner and dog appears to be a necessary condition, but not a sufficient one, for the development of both reactive separation distress and CDA. A common link shared by these social behavior problems is the presence of conflict-related stress and panic occurring in association with the loss of comfort and safety (security). In the case of separation-distress syndrome, the loss of the attachment object at separation provokes varying degrees of distress under the coactive influences of anxiety, frustration, and panic, whereas, in the case of CDA, a loss of safety resulting from provocative stimulation at the hands of an attachment object may result in varying degrees of vulnerability and conflict under the coactive influences of anger, fear, panic, and rage (Figure 7.2). As an object of attachment, comfort, and safety, the owner may evoke significant conflict in the dog when delivering physical punishment producing high levels of pain and fear (see *Drive Systems, Aggression, and Behavior Problems* in Chapter 6), potentially resulting in a dramatic and permanent loss of security and trust. The potential for loss of trust and panic-related aggression is particularly high in situations involving abusive and inescapable punishment directed toward dogs with reactive temperaments (low fear/low anger threshold). As the result of traumatic stimulation and loss of trust, persistent toxic expectancies may form and mediate the expression of panic-related aggression in response to conditioned social stimuli present during the traumatic event. According to

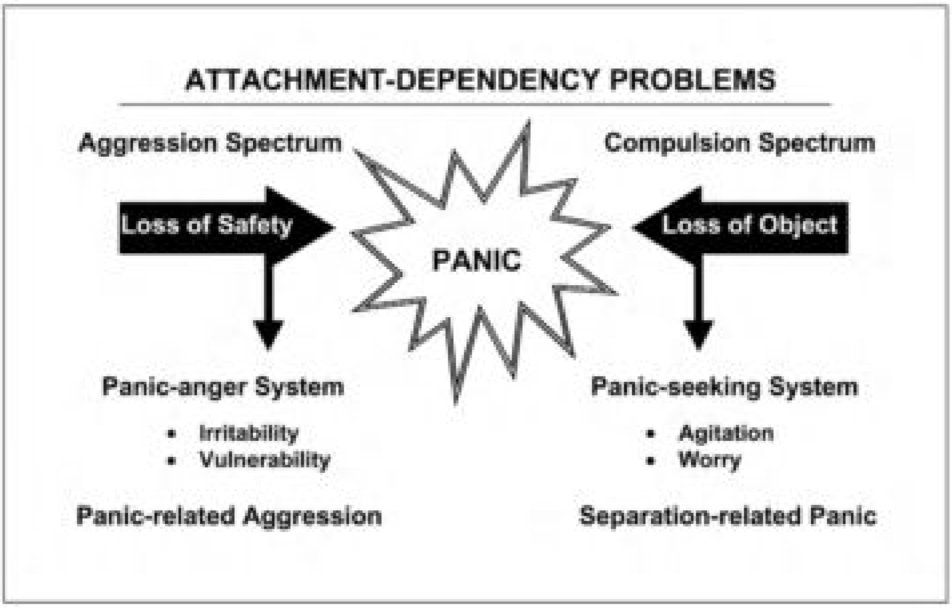

FIG. 7.2. Panic may play a pivotal role in the etiology of severe separation-related distress problems as well as certain presentations of owner-directed aggression, commonly described as dominance related. Both behavior problems appear to involve predisposing biogenetic, developmental, and experiential (e.g., toxic expectancies) influences that render a dog persistently vulnerable to attachment-related loss in association with owner separation (loss of object) or owner intrusions or interference (loss of comfort or safety). Following the emotional command system devised by Panksepp, separation-related distress may acquire an exaggerated and compulsive form as the result of panic-induced dysregulation affecting the seeking system (compulsive spectrum), whereas panic-related aggression may result in exaggerated and impulsive-episodic aggressive behavior (aggression spectrum) occurring as the result of panic-induced dysregulation of the anger-rage system. Both separation distress-panic and panic-related aggression tend to escalate dramatically under the excitatory influence of fear in contrast to the inhibitory effect that fear tends to produce on presentations of separation distress and owner-directed aggression not under the influence of panic.

the panic theory of CDA, provocative stimulation resulting in the loss of trust by a familiar social object may result in heightened autonomic arousal, the precipitous activation of anger-panic circuits, and the eduction of a momentary loss of control over aggressive impulses. Under the influence of panic, predisposed dogs may threaten or attack with bites of varying magnitude, but frequently resulting in grossly exaggerated and uninhibited bites. Many panic aggressors exhibit a distinctive red-glow or glazed-eye look in anticipation of an attack, indicating intense sympathetic arousal. In addition to heightened autonomic arousal, panic aggressors often appear fearless, belying the anger-induced nature of such attacks. Owners of panic aggressors often describe attacks as being out of character and inappropriate with respect to provoking stimulation.

Although an element of familiarity and affection (attachment) appears to be a necessary precondition for panic-related aggression to develop, many dogs form close attachments with balefully cruel owners and endure egregious violations of safety and loss of comfort without ever losing control and attacking their tormentors. In some cases, the dog may feel helpless and may simply passively absorb the abuse, perhaps redirecting it at some point with a vengeance toward an unsuspecting and innocent victim that comes into contact with

the dog. In other cases, the tolerance exhibited by such dogs may be under the protection of biogenetic and developmental influences that promote elevated aggression thresholds (see *Phylogenesis, Polymorphism, and Coping Styles* in Chapter 6). Finally, the tolerance of some of these dogs for the loss of safety and comfort may be the result of a highly flexible bond structure that prevents the violation of trust as a result of threatening treatment (see *Cynopraxis, Antistress, and a Tend-and-Befriend System* in Chapter 6). These observations suggest the possibility that panic-related aggression may depend on an attachment that lacks a trust-forming or trust-protecting bond structure. The failure of such dogs to form flexible and tolerant relationships based on feelings of safety and trust may reflect the influence of inadequate or inappropriate socialization and training efforts (see *Drive Systems, Aggression, and Behavior Problems*). Such dogs may also be affected by biogenetic and developmental deficiencies that contribute to their inability to form viable and trusting bonds with their owners (see *Origin of Reactive versus Adaptive Coping Styles* in Chapter 4). In particular, dogs exhibiting low anger and fear thresholds from an early age may be especially prone to develop explosive panic-related aggression problems in adulthood (see *Behavioral Thresholds and Aggression* in Volume 2, Chapter 8).

Attacks associated with panic appear to be produced by an energetic synergy of anger and fear, perhaps resulting from a traumatic cross-association of anger and fear systems during a sensitive period of neurobiological development. The simultaneous elicitation of anger and fear is hypothesized to mobilize an all-out attack or rage response. Retaliatory punishment directed against impulsive aggression may release a more serious panic-driven attack. Instead of reducing the future risk of aggression, punishment may only worsen the situation by establishing conditioned triggers that cross-associate fear and anger circuits so that activating the one activates the other. The simultaneous elicitation of fear and anger by conditioned triggers may help to explain the exaggerated and disproportionate nature of such attacks.

Even innocuous interaction with family members may be highly stressful for such dogs. Under the influence of benign threats, anxiety may excite anger via cross-associations with fear circuits, which in turn may trigger more anxiety and set into motion a rapid escalation of aggressive arousal until a point of panic and dyscontrol is reached and a hard bite is delivered. In the case of proactive aggression, anger is an emotional establishing operation, recruiting a confrontational sequence. When adaptively aroused, anger is precisely calibrated and matched to the needs of the situation and adjusted in real time. This ability to monitor and adjust aggressive arousal and output depends on the presence of prediction-control expectancies and comparator-feedback networks assessing sensory input for prediction discrepancies. Under normal circumstances, worse-than-expected outcomes shift emotional establishing operations toward adjustments that increase agonistic risk or reduce it. These adjustments to negative prediction error are made under the influence of frustration (anger increasing) and anxiety (fear increasing). Under adaptive circumstances, frustration increases readiness for intensifying aggressive output (fight), whereas anxiety increases vigilance for threats and prepares a dog for fearful retreat (flight).

Under conflictive situations involving a collision of fight and flight vectors, a reactive response based on a slight shift of frustration or anxiety may cause a predisposed dog to attack or retreat, that is, result in a rapid and extreme *catastrophic* adjustment, not just making it more vigilant and ready. According to Zeeman's (1976) catastrophic model of canine aggression, a dog experiencing high levels of anger and fear has only two options available to it: fight or flight. However, such extreme adjustments to situations posing significant unknowns and risk would be adaptive only under circumstances where the cost (risk of injury or loss of social benefits) was significantly outweighed by the potential benefits of succeeding. Consequently, agonistic conflict situations brought on by escalating anger and fear may also be resolved by a third alternative: mutual forbearance and compromise. Instead of relying on catastrophic adjust-

ments, the conflict situation is optimally resolved by mutually disengaging and cutting off animosities, compromising, and engaging in mutually reassuring and comforting reconciliation rituals. Such a strategy of mutual forbearance avoids the potential harm done if the conflict were allowed to escalate into an active fight or flight situation. Whether an agonistic conflict escalates into a reactive situation or not is often determined by the owner's capacity to lead, the quality and strength of the relationship, the social dynamics and stability of the family, the presence of trust, and an established history of the dyad resolving and reconciling differences amicably: "Every reconciled conflict is a choice against entropy" (De Waal, 1996:165). As the result of a tend-and-befriend leadership style and the competent management of conflict and reconciliation, the dog acquires emotional expectations and behavioral adjustment strategies that are incompatible with escalating anger or fearful arousal when exposed to social conflict (threats or challenges). Instead of confronting or retreating, the dog learns to flirt and forbear when experiencing anxiety or frustration in conflictive situations. If instead of encouraging compromise, forbearance, and reconciliation, the dog is severely punished and prevented by force from escaping at such times, it may attempt to break free by biting. In any case, the dog will lose its ability to trust the owner in proportion to the frequency, severity, and uncontrollability of such punishment. Instead of learning to inhibit aggression as the result of such treatment, the dog may attack more readily in the future under the influence of a cost-benefit assessment that now includes a self-preservation incentive; that is, the dog may struggle and fight as though its life depended on it.

Although Zeeman's catastrophe model may provide a useful set of predictions concerning reactive adjustments to conflictive situations involving escalating anger or fear, especially conflicts occurring between strangers exhibiting approximately the same anger and fear thresholds, the model does not offer much empirical or predictive value with respect to adaptive adjustments exhibited by dogs responding under the influence of divergent social dynamics (e.g., relative familiarity, affection, and trust) affecting their agonistic readiness to confront or retreat when aroused with anger or fear. In addition to not providing a cutoff option or an adaptive flirt-and-forbear strategy to cope with escalating anger and fear, Zeeman's model does not appear to predict the passive response of dogs expressing high anger and fear thresholds. Such dogs may neither attack nor retreat, but may instead respond to increasing anger and fear by becoming immobile (freeze) and wait for the aversive situation to change.

Similarly, depressed human patients frequently exhibit reduced positive affect together with episodic anger attacks that are frequently described as being uncharacteristic of their typical demeanor and out of accord with the provoking situation. Anger attacks occurring in association with depression resemble human panic attacks but without the prominent influence of fear and anxiety (Fava and Rosenbaum, 1998). Finally, perpetrators of domestic violence are often affected by a precipitous increase of autonomic arousal and loss of control occurring in association with violent attacks. The investigation of domestic violence reveals intriguing parallels with significant potential implications for understanding panic-related aggression in dogs (see *Autonomic Arousal, Heart Rate, and Aggression* in Chapter 6).

Both panic-related and avoidance-related types of aggression are often lumped together under the heading of dominance aggression. Although some superficial similarities exist, panic-related aggression and aggression associated with anxiety and avoidance differ from each other in several important respects. Panic-related aggression is most commonly directed against family members or others with whom the dog is closely familiar and otherwise affectionate toward, whereas avoidance-related or avoidance-*motivated* aggression is often directed against both family members and others with whom the dog is not familiar or on friendly terms (see *Avoidance Learning and Aggression* in Volume 2, Chapter 6). Panic-related aggression rapidly escalates under the excitatory influence of coactive anxiety and fear, to reflect a reactive

loss of executive control over aggressive impulses. Avoidance-related aggression, on the other hand, is primarily of a defensive origin, but can be intensified under the secondary influence of anger and success, causing it to become progressively brave and preemptive. Panic-related aggression and avoidance-related aggression also differ in terms of the degree of control that a dog has over its aggressive impulses. Whereas panic-related aggression presents in ways that indicate compromised impulse control and a high level of autonomic arousal (e.g., fitlike attacks and red glow in the eyes), avoidance-related aggression usually occurs under the influence of significant impulse control, with avoidance threats and bites delivered under the influence of control-related incentives and expectancies. In contrast to the reactive and hard biting of panic aggressors, avoidance aggressors more often show well-targeted and inhibited bites, air snapping, and fang whacking, and much less frequently produce serious bites. Avoidance-related aggression is often associated with signs of conflict (threats), whereas panic-related aggression is more impulsive and often performed with little or no warning. Finally, unlike panic-related aggression, avoidance-related aggression is much more sensitive and responsive to the effects of reward and punishment. Consequently, whereas avoidance-related aggression falls under the category of control-related or proactive aggression, panic-related aggression is placed under the heading of impulsive or reactive aggression (see *Panic, Impulsivity, and Episodic Dyscontrol* in Chapter 8).

PART 2: ASSESSING AND TREATING CANINE DOMESTIC AGGRESSION

CANINE DOMESTIC AGGRESSION: ASSESSING THE THREAT

Dogs that bite family members defy simple characterization, exhibiting a wide spectrum of social traits and behavioral histories. Aggressive dogs may appear to be socially independent and aloof, serious-minded, depressed, or moody. However, depression and lack of positive affect are not representative of all canine aggressors. In fact, many owners of biting dogs report that the dogs are genuinely affectionate and playful most of the time (Borchelt, 1983), but rapidly shift from an affectionate mode of interaction to become distant, irritable, and threatening. Many owners report that aggressors show contrition or signs of remorsefulness following an aggressive episode (Voith and Borchelt, 1982). Typically, the aggressor threatens or attacks only when it perceives a challenge or imminent threat to its control over some situation. Aggressive dogs may exhibit a variety of threatening displays, such as direct staring, growling, snarling, stiffening, raised hackles, air snapping, and inhibited biting, prior to actually delivering an overt attack. Some aggressors do not show any reliable signs or warnings at all in anticipation of an impending attack. Although aggressors sometimes bite hard and cause severe injuries, the majority of domestic dog bites are inhibited punitive snaps, aimed at controlling irritating, frustrating, or threatening stimulation.

Deciding to Accept a Case

Cases involving aggression directed toward family members involve many factors that should be carefully considered before accepting such cases. In addition to assessing the severity of the aggression problem, the cynopraxic counselor should evaluate the owner's attitude and the general family situation. Are children at risk in the household? How cognizant and responsible is the owner about the potential danger posed by the dog? Can the owner be realistically expected to carry out training procedures and follow through on a long-term basis? What are the odds of a lasting success and management of the problem? Unless the overall picture is one where benefits significantly outweigh hazards, the trainer should decline services and redirect the case back to the referring veterinarian.

If the case is accepted, the owner should be carefully informed of the risks involved, including the fact that long-term treatment outcomes are unknown and, although improvement should be expected and main-

tained, the risk of a future bite incident cannot be entirely eliminated despite the most conscientious and expert training. Currently, a wide range of treatment options exist, often containing conflicting rationales and recommendations with varying degrees of scientific legitimacy and therapeutic value. Voith and Borchelt (1982) observed early on the rather protean nature of the treatment process, stressing that no one technique is likely to work in all situations:

> There are, literally, an infinite number of variations on behavioral techniques for treating dominance aggression … There are no specific techniques that work in all situations. In order to achieve a high rate of success, individual programs that require constant refinement should be designed for each case. There are no inflexible rules on how to respond in specific circumstances. (659)

These observations were written nearly 20 years ago but remain relevant today. At the outset of the training process, owners should be informed that none of the current behavioral protocols used for controlling and managing dominance-related aggression have been rigorously evaluated for efficacy. Despite the absence of definitive studies, preliminary work indicates that a variable therapeutic benefit is achievable in many cases. For example, Uchida and colleagues (1997) performed a follow-up study to evaluate the benefits of an 8-week program of nonconfrontational training on 20 dogs diagnosed with dominance aggression. The follow-up showed that 20% of the owners questioned believed that their dogs had been "cured," while another 30% of them indicated that a "marked improvement" had occurred as the result of the training process. Takeuchi and colleagues (2001) found that 51.2% of owners with dogs exhibiting dominance aggression (N = 82) reported that their dogs showed improvement as the result of behavioral treatment. Reisner and colleagues (1994) reported that 85% of owners with dogs diagnosed with dominance aggression observed some improvement in their dogs' behavior as the result of treatment. Similarly, Line and Voith (1986) found that 16 of 19 owners of dominance aggressors observed improvement, with 13 of them indicating either very much or significant improvement. The extent to which these reports of improvement are attributable to actual changes in behavior due to behavioral training or due to various indeterminate factors such as placebo effect, a desire to please an authority figure, or denial has not been objectively assessed. Given the current state of the art, if pressed for a prognosis regarding a dog with a history of CDA, ethical counselors can only state with confidence that most cases of such aggression can be successfully treated with an expectation of stabilization and improvement, but there is no cure and the risk of future attacks cannot be entirely eliminated. Dog owners must be made acutely aware of these limitations and risks before training is begun.

Treatable versus Untreatable Aggression Problems

Canine domestic aggression presents with a high degree of variability with respect to targets, severity, location, and predictability of attacks. These variables need to be carefully assessed to evaluate the risk of serious injury or permanent scarring to family members (Table 7.2). The target and relative frequency, location, severity, and predictability of attacks determine the viability of behavioral intervention and likely prognosis. Intrafamilial attacks that occur on an unpredictable basis or with minimum provocation pose special difficulties. In cases where severe bites have occurred with little or no provocation or warning, professional training services should be withheld or only cautiously provided, and then primarily to advise the owners about the risks and instruct them on how to avoid eliciting circumstances and to introduce preventive management techniques. Because of the unpredictable nature of the attacks, it is difficult, if not impossible, to assess the benefits of training or to evaluate future risks safely without exposing family members and visitors to a potential bite, thus making such cases by definition "untreatable." Further, in the case of unpredictable aggression, the absence of aggression for some period is no reliable indi-

TABLE 7.2. Aggression ranked in accordance with predictability, frequency, severity, and location of threat or attack

1. Threatening stare and growling
2. Snarling and air snapping
3. Muzzle jabbing and fang whacking
4. Inhibited biting
5. Inhibited biting with bruising
6. Inhibited biting with slight puncture to extremities and torso
7. Inhibited biting with slight puncture to the head
8. Infrequent, but predictable, hard puncture biting delivered to the extremities
9. Infrequent, but predictable, hard puncture biting delivered to the torso
10. Infrequent, but predictable, hard puncture biting delivered to the head
11. Frequent, but predictable, hard puncture biting
12. Infrequent and unpredictable hard puncture biting
13. Frequent and unpredictable hard puncture biting
14. Puncture biting with head shaking and laceration
15. Sustained attacks involving multiple punctures and lacerations

cator that it will not unexpectedly recur at some point (see *Dead-dog Rule* in Volume 2, Chapter 2). Domestic aggression involving severe and unprovoked attacks is often tragically refractory and improvement notoriously transient and labile. Despite the most determined and conscientious training efforts, dogs that bite are at a significant risk for repeating the behavior—a fact that many dog owners eventually forget about over time with disastrous results. Consequently, given the obvious risk to public safety, one cannot rationally justify the treatment of dogs exhibiting severe uninhibited attacks or unpredictable aggression. Dogs exhibiting uninhibited or unpredictable hard biting should be referred to the family's veterinarian for medical evaluation and final disposition. In contrast, treatable CDA is associated with clear warning signals and precursor behaviors, such as direct staring, growling, snarling, and preparatory stiffening, with the dog biting only as a last resort when all else fails to control the situation. When the dog does bite, it is usually inhibited and causes minor trauma, if any. This form of CDA is much more responsive to management and behavior-therapy efforts and has a better prognosis, but it remains technically incurable and its remission depends on a lifelong commitment to management and training.

The absence of a permanent cure and the tendency of aggression to recur may account for the routine euthanasia of dogs diagnosed with dominance aggression. Such a blanket euthanasia policy is inappropriate, however, since many dogs exhibiting CDA can be effectively trained and managed as the result of relatively brief interventions and owner education. In addition, some forms of CDA are significantly influenced by treatable medical conditions that should be excluded before euthanasia is considered. In the absence of medical causes, the decision to euthanize a dog should be based on a formula weighing the severity and location of bites, the frequency and predictability of the attacks, and the composition of household, especially the presence of young children at risk. In addition, a realistic assessment of the owner's ability to carry out training and management recommendations should be objectively considered when faced with such decisions. Unpredictable, frequent, severe bites directed

toward the face or torso weigh strongly in the direction of euthanasia, whereas highly predictable, infrequent, inhibited bites directed to the hands weigh strongly in favor of treatment, at least in the case of homes not occupied by young children. The presence of young children significantly complicates matters, since children are often unable to follow instructions consistently to avoid interaction that might evoke aggression. In homes with young children, dogs exhibiting an established propensity for highly predictable and inhibited aggression toward children should be evaluated for rehoming. Most cases of aggression present with bite patterns that lie somewhere between the opposite extremes of severe, frequent, and unpredictable attacks and infrequent and predictable threats or inhibited bites, requiring objective assessment and evaluation on an individual basis to determine the viability of behavioral intervention.

The diagnosis of dominance aggression is problematic and lacks a universal and coherent set of inclusion and exclusion criteria, with considerable debate and controversy surrounding what is meant by the category. In general, what is referred to as dominance aggression in the literature seems to be deeply and insurmountably confused, representing a significant obstacle to research and the treatment of such problems. The notion of a dominance drive causing a dog to threaten or bite family members in order to achieve a superior rank is particularly problematic, since it is commonly used to justify interactive punishment—a training strategy that is tantamount to treating a burn with hot water. The spectrum of aggressive behaviors linked under the rubric of dominance aggression is more akin to involuntary subordination, social incompetence, reactive impulsivity, powerlessness, and panic rather than social dominance (see *Social Competition, Cooperation, Conflict, and Resentment*). The dominance hypothesis of CDA has not been established convincingly nor is it consistent with the generally obligatory subordinate and dependent nature of the relations between people and dogs. Identifying and controlling resources (e.g., food, affection, and play) of interest to a dog can more easily, rapidly, and safely produce active-submission behavior than force. Setting limits while methodically gratifying submissive behavior (begging) with the contingent delivery of rewards is conducive to the integration of leader-follower cooperation and friendly relations via competent dominance, leadership, and nurturance (see *Filial and Sibling Dominance-Submission Relations*).

Consequently, instead of placing undue and unjustifiable etiological emphasis on a dog's striving to achieve social dominance over the owner as a cause of aggression, cynopraxic treatment programs are better served by reinforcing active cooperation, reducing or removing adverse emotional influences known to lower or destabilize aggression thresholds, and avoiding provocative interaction that might trigger FFS arousal and reactive threats or attacks. Further, instead of emphasizing confrontational and coercive procedures aimed at suppressing aggression or reducing the dog's social rank by force and defeat, training efforts should be dedicated to increasing the dog's social competence by means of reward-based training, with the goal of improving attention and impulse control and shaping prosocial behavior under the influence of dependable prediction-control expectancies and emotional establishing operations incompatible with aggression. In addition to establishing useful control over the dog's behavior, such training efforts serve to mobilize an antistress response, helping to reduce irritability, intolerance, and reactivity, thereby improving the dog's ability to cope adaptively with stressful social interaction (see *Cynopraxis, Antistress, and a Tend-and-Befriend System* in Chapter 6).

Affiliative Conflicts and the Rise of Agonistic Competition

Owner Attitude and Personality, Spoiling, and Anthropomorphism

Owners lacking assertive and confident personalities have been implicated in the etiology of aggression problems. According to Beaver (1999), CDA problems often develop as the result of a mismatch of personality types between the owner and the dog, with timid owners being at a greater risk of falling victim to the aggression of a "dominant type" dog. Hart and Hart (1997) have expressed similar

opinions, suggesting that puppies exhibiting signs of aggression should be "admonished or punished sufficiently so as to subdue the reaction, as long as the owners are safe from being bitten or injured" (1132). Hart and Hart (1985) have also suggested that pampering and spoiling activities play a significant role in the development of CDA problems. Voith and colleagues (1992) have disputed the role of spoiling activities and anthropomorphic attitudes in the etiology of aggression problems. For example, they found that behavior problems (including dominance aggression) appear to occur independently of spoiling activities (permitting a dog to sleep on the bed, giving it noncontingent treats, and sharing food from the table), anthropomorphism, and past obedience training (see *Excessive Indulgence* in Volume 2, Chapter 2):

> Taken together, the results of our analyses clearly and consistently failed to show any support for the notion that dogs that are "spoiled," treated like a person, or not obedience trained are more likely to engage in problem behaviors. In fact, the results … revealed that dogs taken on trips or that received shared snacks or food from the table were significantly less likely to engage in behavior problems. (270)

Although the data linking owner attitudes with the development of aggression problems are sparse and conflicting, some reports suggest that the amount of owner experience with dogs, emotional orientation, and the presence of anthropomorphic attitudes may affect the development and treatment of canine aggression problems (see *Psychological Factors* in Volume 2, Chapter 10). For example, in contrast to the aforementioned findings of Voith and colleagues, O'Farrell (1995) has suggested that owners exhibiting anthropomorphic emotional attachments toward their dogs may be at a greater risk of becoming the target of dominance-related aggression problems; unfortunately, O'Farrell's notion of *dominance* itself appears to be steeped in anthropomorphic assumptions and generalizations about the social functions of dominance and submission behavior. Jagoe and Serpell (1996) found that first-time dog owners are more likely to experience a variety of behavior problems, including disobedience, excessive excitability, and a variety of dominance-related aggression problems. Similarly, Kobelt and colleagues (2003) have linked first-time ownership with reports of increased excitability and nervousness in dogs. Younger owners lacking breed knowledge and experience with dogs appear to be more likely to rear dogs showing aggression and other problems than are older, more knowledgeable, and experienced dog owners (Rugbjerg et al., 2003). Many owners may be fearful of their dog following an attack, making treatment difficult (Manteca, 1998). Some owners appear to be alternately angry or afraid of their aggressive dogs, often leading to disorganized and inappropriate training activities. Relevantly, Dodman and colleagues (1996a) found that thinking-type owners were more likely to succeed in treating dominance-related aggression than were feeling-type owners (see *Psychological Factors* in Volume 2, Chapter 10). Finally, Guy and colleagues (2001b) have suggested that allowing the puppy to sleep on the bed during the first couple months of ownership may be associated with an increased risk of aggression problems.

Dominance, Social Distance and Polarity, and Begging for Love

Among wolves living under natural conditions, the finding, ownership, and distribution of food are important prerogatives of dominance, with active submission representing little more than a food-begging ritual (Mech, 1999; Schenkel, 1967) (see *Wolf Model of Dominance and Submission*). Also, active-submission behaviors and begging for social contact and affection (attention-seeking behavior) are also forms of subordinate behavior, whereas receiving such behavior tolerantly and guiding it into socially constructive outlets is an expression of competent leadership. Submissive seeking is a natural concomitant of reward training and appears to play a significant role in the formation of dominant-subordinate relations resulting from ICT. Setting limits and providing rewards on the basis of a contingency or rule prevents seeking behavior from becoming obtrusive while at

the same time facilitating a VSS. According to this interpretation, the dog is an obligate subordinate, and domestic aggression is most often due to social incompetence developing in association with an ISS, that is, a reactive coping style and preferential responsiveness to signals of punishment and loss. At bare minimum, simply requiring that dogs not become obtrusive while seeking gratification, and that they give their attention to family members by way of submissive "asking" behaviors before they are rewarded, appears be sufficient to maintain subordinate and friendly relations.

In cases where a long-standing history of indulgence and affectionate submission is directed toward the dog by family members (see *Dominance: Status or Control* in Volume 2, Chapter 8), a VSS based on submissive seeking and leadership may fail to develop or may develop in association with significant conflict. In the absence of appropriate social polarity and distance, the dog may show signs of increasing irritability, intolerance, and reactive biting (incompetence) in response to owner interference and intrusion (see *Social Distance and Polarity* in Volume 2, Chapter 8). The excessive affection, handling, and petting given to such a dog may activate nascent dominance dynamics, especially in cases where the dog is given such attention without actively seeking or welcoming it.

Affectionate contact is something that many owners crave and obtain from dogs by means of affectionate solicitation (sweet talk), handling (hugging and picking up), and petting. In an important sense, providing affectionate gratification to family members is a resource that a dog can own and limit access. When affectionate contact is not invited or welcomed, the dog may interpret the family's affectionate efforts as intrusive submissive care-seeking activity rather than care-giving activity; that is, the owner's affectionate contact may be viewed as submissive *begging for love*, to borrow Schenkel's terminology (Schenkel, 1967). This hypothetical reversal of roles associated with affection seeking and giving may generate intolerance, especially with regard to the unwelcome handling and petting provided by least-preferred family members, perhaps triggering the dog's incompetent aggressive efforts to advertise ownership or to set limits on such interaction by threatening or biting them. Retaliation by the owner against such threats may subsequently set into motion an ISS, resentment, and heightened sensitivity to signals of punishment and loss. As the result of unwelcome familial affection-seeking behavior and subsequent punishment in response to the dog's threats, social polarity may be conflicted, with the dog exhibiting behavior toward family members consistent the classical signs of dominance-related aggression. Conflictive dynamics between dominance and submission may be further elaborated and integrated into the relationship by means of incompetent family control efforts (e.g., bribing, cajoling, crouching, repeating, and tricking). Instead of controlling the dog in a confident and friendly way, the owner's control efforts may take on a nervous and begging quality and significance for the dog. By bribing, cajoling, and entreating the dog to cooperate, the owner transfers the locus of control to the dog by allowing it to decide whether to comply. In such cases, the dog appears to reward the preferred owner's submissive asking behavior with compliant tolerance, but may show a lack of responsiveness to less-preferred family members despite their similar submissive strategies. However, regardless of preference, if a family member attempts to force the dog to comply with a stern voice or hand, the dog may actively resist, threaten, or bite hard.

Without identifying and substantially changing the interactive dynamics fostering the development of CDA, it is unlikely that contact aversion, resentment, and propensity for biting can be significantly modified. To promote submissive behavior and a VSS, the family must establish ownership and leadership with respect to significant resources, including the gratification associated with affectionate petting and handling. The key to treating such aggression problems is establishing social distance and systematically reversing social polarity, so that the dog is encouraged to seek affection, play, and rewards from family members while integrating friendly relations with everyone in the household. In

addition to helping the owner understand the problem, an improved relationship based on a balance of dominance, leadership, and nurturance is facilitated by means of ICT. The cynopraxic process is carried out simultaneously on several levels with the goal of providing the owner support, knowledge, practical advice, and a model for more appropriate and friendly interaction with the dog (Table 7.3). Some owners appear to be so emotionally dependent and submissive toward their dogs for affectionate gratification that they accept the occasional bite in order to maintain the relationship. Such owners may also carefully avoid punishing the dog for fear of losing its affection. Such owners of aggressive dogs are also prone to engage in denial and magical thinking about the problem, requiring that the cynopraxist stay on guard for *subterfuge* (protecting the dog by not revealing vital information), *sabotage* (not carrying out the training recommendations), and *slippage* (reverting back to previous patterns of interaction with the dog).

To restore control, such dogs should be appropriately restrained to make them safe to interact with family members. At a minimum, dogs with a history of CDA should be kept on a collar and leash. The dog should be trained to orient on signal (e.g., smooch or squeak). As the dog shifts its attention (target arc), a click or "Good" is delivered and followed by a flick of the right hand to the side. Although, in general, small rewards are preferred, a larger and highly desirable food item can be given intermittently to the dog during the process of training it to approach. As the dog approaches the closed hand, the trainer says "Good" and opens it to reveal the reward. Initially, both the right and left hands are flicked out to the side. The sharp flicking movement of the hand is designed to attract the dog's attention while reducing reactive associations with fast-moving hands. Feeding the dog by hand is a viable way to restore confidence and reduce potential adverse associations associated with past rough handling or hitting. The hand should be flicked to the side, not toward the dog. In addition, a scented squeaker bulb can be held in the hand and gently squeezed (without squeaking) to deliver the dilute scent of orange or lavender just before the hand is opened. Tactile-target-arc training can be performed by getting the dog to orient to a gentle nonthreatening touch followed immediately by the conditioned odor alone or combined with the squeak or smooch sound. Such training appears to help integrate new sensory associations and input at the level of the sensory analyzer and gating channels leading to higher cognitive and emotional processing.

Gradually, the dog is required to look into the trainer's eyes for variable periods before the trainer says "OK" and flicks the right hand to the side, thereby causing the dog to break eye contact. The dog's name can be paired with the orienting signal and the vocal

Table 7.3. Elements of cynopraxic mediation and counseling

Respond sincerely and sympathetically to the owner's concerns about the dog's behavior.
Emphasize the positive aspects of the relationship and constructively frame the problem in the context of achievable goals.
Provide an authoritative and objective evaluation of the problem in both functional and interpersonal terms.
Discuss and clarify the dog's biobehavioral needs and provide practical ways of satisfying them.
Discuss possible social and environmental causes contributing to the problem.
Introduce scientifically sound behavioral principles for understanding and controlling or managing the problem behavior.
Demonstrate cynopraxic training procedures, stressing the importance of predictable and controllable training events to promote comfort, safety, and trust.
Provide the owner with a positive role model for interacting with the dog.

signal "Come" can be overlapped with the approach. These components are foundations that all family members can practice with the dog. Children are instructed to avoid directly approaching the dog, but may use the foregoing procedure in an abbreviated way (e.g., dog's name, smooch, flick the hand, "Good," and food reward) to encourage the dog to approach or follow them. Approximately half of the dog's daily ration should be fed by hand, with the dog approaching the child and the parent from various distances. The orienting, frontal approach, and sustained attending responses systematically integrate the social engagement system, serving to establish highly predictable and controllable interaction that is emotionally incompatible with aggression. As things progress, the dog will become more approachable and receptive to contact as the scripting of friendly roles and expectancies of reward are established. Training the dog to approach is an extremely useful procedure for changing the direction of attention and social polarity and managing potentially provocative situations. In situations where the dog shows signs of arousal, the trainer can back away and trigger the orienting response, bridge it, and perform the flick signal to bring about a friendly resolution of the conflict. Initiating cutoffs, integrating alternative behaviors incompatible with aggression, and performing a reconciliation ritual can be helpful in the management of many CDA problems (see *Loss of Safety, Depression, Panic, and Aggression*).

An adaptive coping style and VSS are further facilitated by means of shaping (see *Shaping: Training through Successive Approximations* in Volume 1, Chapter 7). The procedure offers many significant benefits in the training of dogs showing adjustment problems associated with social incompetence and a reactive coping style. Shaping procedures are highly beneficial in this regard because they explicitly shift the locus of control over significant events (reward and punishment) from the trainer's initiative and prompting to the voluntary initiative and experimentation of the dog. Excessive reliance on command-and-response training may foster an undesirable continuation of dependency on the owner for obtaining comfort and safety, perhaps merely complicating the situation with another layer of behavioral entrapment and loss of freedom. Consequently, in addition to structured ICT and attention therapy, strong emphasis is placed on rewarding constructive initiative (offered behaviors) and active participation via shaping and play. Shaping is eminently compatible with cynopraxic training and therapy objectives (see *Prediction Dissonance and Shaping* in Chapter 10). During the shaping process, the dog's behavior is intensively differentiated and organized in accordance with the formation of instrumental prediction-control modules, calibrated appetitive and emotional establishing operations, and emergent adaptive modal strategies. As a result, shaping provides a potent source of somatic and cortical reward in the process of developing socially adaptive control modules and modal strategies. In addition to learning new behaviors, already established basic obedience modules and routines can be retrained by breaking them down into approximate components and steps for the dog to learn via the shaping. Offered responses need not precisely match the trained module or routine to warrant reward, but can be taken as a starting point for shaping. By waiting and giving the dog a fair chance to offer an appropriate behavior or learn to experiment without risk of punishment, the dog's sense of control, competence, and confidence is gradually improved and its trust enhanced. Patiently waiting and rewarding offered behavior or providing supportive guidance during the shaping process helps to improve the owner's leadership skills while increasing the owner's appreciation of the dog as learner.

Nothing in Life Is Free, Subordinate Postures, and Rank

During the 1970s, Voith (1977) explored the possibility of treating dominance-related CDA by means of a reward-based training protocol. Historically, this was a significant departure from earlier training methods based on the force-based concept of wolf and dog dominance hierarchies popularized in the writings of Lorenz (1955). Believing that CDA was primarily the result of dominance incentives operating within the household, she explored the possibility of altering the status of domes-

tic aggressors by reinforcing subordinate postures (e.g., sit, lie down, and roll over) with food and a variety of everyday rewards (petting, play, opportunities to go outside, and so forth) in accordance with a "nothing in life is free" (NILIF) program. Once the dominance hierarchy was reversed by means of NILIF and graduated exposure to mildly provocative handling, owners were instructed to counteract growling and other threats by moving back and staring the dog down from a safe distance (Voith and Borchelt, 1982):

> Establishing the maxim that "nothing in life is free" is a means of subtly reversing a dominance hierarchy by requiring the dog to assume progressively more submissive postures before it gets anything it wants. If the dog indicates it wants to be petted, to go out, to come in, or to play, it must, for instance, sit before it is allowed to engage in the activity. Later, it may be requested to lie down, roll over, or gradually tolerate pressure on its back or muzzle before it is permitted access to what it wants. (659)

The NILIF program has been applied in various ways to treat dominance-related aggression and other common behavior problems. Despite its widespread use, scant research has been performed to test the hypothesis that positive reinforcement of submissive postures can help to reverse an established dominance hierarchy. Tortora (1980) reported some data obtained from a case study in which submissive behavior was selectively rewarded in an effort to reduce aggression in an 18-month-old bullmastiff. The dog exhibited a variety of aggressive behaviors toward family members and attacked several persons not belonging to the household, including a severe attack resulting in 11 stitches to one of the victims. The treatment program consisted of first reinforcing various submissive facial expressions and then shaping a progression of bodily postures leading to the dog rolling on its back and allowing the owners to put their hands around the dog's neck. Each facial expression and posture was prompted and paired with the vocal signal "Quiet." The rewards given to the dog consisted of attention and kibble. The submission training was carried out daily over the course of 20 days, with the dog reportedly showing a dramatic reduction of threatening behavior. The improvement was still evident after a 6-month follow-up, despite inconsistent training efforts by the owners. Unfortunately, the significance of the foregoing case study is difficult to assess since the owners performed the procedures and collected the data. Further, given the severity of the problem and the owners' evident lack of behavioral experience, one cannot help being skeptical about the success reported. Such miraculous improvements are relatively rare in the process of working through serious aggression problems and, in any case, they are the exception rather than the rule. Whether it worked or not, conventional basic obedience procedures incorporate a similar but more systematic and controlled approach to prompting and rewarding compliance and submissive postures in the context of basic training. Combining reward-based training and various behavior-therapy procedures (response prevention, graduated interactive exposure, counterconditioning, TO, and so forth) with a modified NILIF program, integrated compliance training, directive prompting, mechanical manipulation (e.g., PFR training), escape/avoidance training, and play, selected and organized to match the needs of the dog, would seem to offer the needed flexibility and variability to respond to the individual differences and training requirements of the greatest number of dogs.

Other authors have questioned the ability of the NILIF program to reverse established dominance relations. Reisner (1997), for example, has expressed general doubts about the efficacy of behavioral efforts to reverse the household dominance hierarchy, but argues that "altering the dog's perception of rank order should be possible, if only in mild cases, so that conflicts are less likely to occur" (487). The idea that one might be able to alter a dog's perception of rank order without at the same time modifying its actual rank seems to be an extraordinary proposition. Logically, a hierarchical change in dominate-subordinate relations ought to occur before the dog's perception of rank order is modified, for what else other than such an actual change might

sensibly explain the dog's altered perception of rank? Perhaps the statement refers more loosely to changes in interaction that alter the dog's perception of the social rank of family members without necessary changing its rank. In either case, the attribution of causal and therapeutic significance to hypothetical changes made to a dog's perception of rank order without changing its actual rank seems to exchange a difficult-to-prove dominant-rank hypothesis for an even more difficult-to-prove dominant-attitude or *perception-of-rank* hypothesis that is fraught with anthropomorphic pitfalls, potential for attributional error, and risk for pseudoscientific fictionalizing (see *Social Dominance: Dispositional Cause or Attributional Error*). Both of these social dominance notions contain etiological assumptions that are taken for granted as facts instead of unproven hypotheses or, worse yet, untestable beliefs.

In any case, Reisner contends that keeping the dog off furniture and not allowing it to jump up during greetings serve to modify its perception of rank order since "height inflates social rank" (488). The owner is also instructed to forbid the dog from entering the bedroom at night in order to prevent the dog from laying "claim to the owner's resting place" (488). The owner is warned to keep the dog away from the table and to feed it only after the family has eaten, apparently based on the assumption that the alpha eats first and so on. These various assumptions concerning dominance and the dog's perception of rank are problematic and difficult to defend. Interpreting human-dog interactions in terms of wolf social behavior is risky even when it is founded on accurate and complete ethological information. Although a dominant wolf may stand over a cowering subordinate (Van Hooff and Wensig, 1987; Mech, 1999), and such height differences may signify rank in the context of active threat and appeasement exchanges, to my knowledge there is no significant evidence supporting the idea that wolves or dogs advertise rank by claiming and defending elevated places or that they preferentially select such places for an advantage with respect to asserting control over group members. Many perfectly subordinate dogs enjoy resting on furniture, sleeping on beds, taking treats from the table, and affectionately jumping up at greetings under the influence of attention-seeking and comfort-seeking incentives, without ever feeling an urge to threaten or bite family members. Such dogs may become obtrusive and irritating nuisances needful of training, but they rarely show aggression problems or become confused about their social rank. Voith and colleagues (1992) "clearly and consistently" failed to detect a relationship between allowing a dog to engage in the previously mentioned activities and an increased risk of developing behavior problems, including aggression toward family members. The suggestion that feeding the dog second may be helpful to reduce dominance-related problems also appears to be without support; in fact, such a change in feeding order may actually risk increasing aggressive behavior. Jagoe and Serpell (1996) found that deferring the dog's meal until after the family had eaten was positively correlated with an increased risk of territory-related aggression. Dogs that show threats when approached while on furniture or while occupying any other place in the house should be thoroughly desensitized to the owner's approach and trained to jump off furniture on signal and to refrain from getting back up unless invited up first. Also, dogs that have shown overt aggression while on beds should be repeatedly prompted to get on and off the bed until the response is performed fluently and without hesitation. All compliance training should be performed with positive reinforcement in conjunction with minimal leash prompting and brief TO, as needed to de-arouse the dog. Once trained, the dog should be permanently forbidden access to the bed, not because it might engender a misperception of the owner's rank, but simply because it reduces the risk of an aggressive event in the future. Since a significant correlation has been detected with respect to intrafamilial aggression and cosleeping during the first two months after coming into the home (Guy et al., 2001b), puppies should be prevented from sleeping on the bed during the first 2 or 3 months. Finally, as regards jumping up, such behavior is typically

aimed at achieving close contact, intensifying tactile stimulation, and promoting friendly relations. Even when sociable dogs are greeted by crouching down, the owner does not risk losing rank, but rather invites affectionate licking, nudging, and pushing-in behavior and other active-submission behaviors. According to Schenkel (1967), among wolves such behavior may be interpreted as an "overwhelming offer of friendly affection" (324). When crouched down below the dog's eye level, few dogs will attempt to take advantage of the situation in order to advance their status; however, many may be prompted by the action to play, appearing to interpret the lowered posture as an invitation to play (see *Metacommunication and Play* in Volume 2, Chapter 8). Such interaction would be inappropriate and potentially dangerous in the case of an experienced aggressor simply because it places the trainer in a vulnerable position and exchanges an increased risk for a minimal potential benefit—not a wise training decision. Jumping up can become an obtrusive and unwelcome habit if appropriate limits are not set on it, but prompting a friendly dog to jump up is unlikely to adversely affect its perception of rank or promote aggressive behavior.

To further adjust the dog's perception of rank and increase owner control, Reisner (1997 and 1998) recommends an abrupt cessation of all affection and other sources of reward for 2 weeks, during which time family members are instructed not to speak to the dog, pet it, or show it affection. The dog is totally ignored except as necessary to meet its basic needs. During the next 2 weeks, attention and affection are partially restored, but only at the owner's initiative. All attention is given on a contingency basis, requiring that the dog first submit to an obedience command. The dog is only permitted to ask for attention after a month of social deprivation, and then attention is provided contingently on half of the occasions in which the dog solicits it from family members. All rewards are provided on a contingency basis, such that the dog must sit or lie down before being petted, given food and treats, taken for walks, let outdoors, and so forth. Finally, outdoor activities are severely curtailed by exercising the dog on leash, and ideally all off-leash romping in the yard is eliminated. The NILIF program, together with the previously mentioned prohibitions, is embedded into every significant social transaction for the remainder of the dog's life so that family members can dictate control over the dog's "daily decisions." The NILIF process, as described by Reisner, appears intended to externalize the locus of control and thereby undermine the dog's ability to initiate independent actions in search of reward. As such, the program appears to promote an increasing social dependency and powerlessness, whereby the owner dictates what the dog can do and when it can do it while frustrating the dog's ability to produce social reward on its own initiative.

Ironically, although extreme forms of positive punishment have been rightly repudiated, many of the same individuals who admonish dog owners not to use physical punishment show little compunction about hanging the dog out to dry. Whether intended as such or not, the withdraw of social reward is a highly stressful and anxiogenic form of punishment, indiscriminately targeting both desirable and undesirable social behaviors irrespective of what the dog does or does not do. Although both forms of extreme punishment are problematic and deserving of criticism, at least positive punishment is usually applied contingently against a specific target behavior. In contrast, the social-deprivation procedure punishes all social behavior with *inescapable* nonreward, disconfirming previously established prediction-control expectancies, and thereby generating considerable distress and confusion. If the social-deprivation procedure works to reduce aggression, it probably does so by inducing increased social anxiety and psychological stress via a variant form of learned helplessness induced by the abrupt and inescapable loss of control over social rewards (see *Learned Helplessness* in Volume 1, Chapter 9).

Abruptly depriving the dog of basic social and appetitive needs that had have routinely provided for in the past is a provocative shift of social and environmental expectations, potentially exerting a number of problematic

side effects. Social isolation and restraint stress have been shown to increase anxiety and lower reactive thresholds among dogs and laboratory animals (see *Restraint, Unavoidable Aversive Stimulation, and Stress* in Chapter 10). Among rats, brief or acute restraint stress appears to exert an inhibitory effect on aggression, whereas exposure to chronic restraint stress causes rats to become significantly more threatening and hostile toward cagemates. Over the same period (14 to 21 days), nonstressed controls tended to form more friendly and stable relationships, showing significantly less aggressive behavior toward cagemates and no evidence of fighting by the end of the study period (Wood et al., 2003). While brief cold shouldering may pique a dog's interest in social rewards and increase its efforts to restore rewarding exchanges with family members, chronic social deprivation and confinement may risk activating dispersive tensions and entrapment dynamics, perhaps causing domestic aggressors to become increasingly unstable, incompetent, and confrontational around safe havens perceived as under threat.

The chronic stress associated with the social-deprivation procedure may generate a significant challenge to the dog's coping capacities and behavioral integrity, probably increasing its dependency while further reducing its ability to competently initiate and organize social behavior, impeding its ability to learn efficiently, and thwarting the *attentionis egens* mediating positive human-dog affiliation (Odendaal and Meintjes, 2003). The noncontingent loss of control over appetitive and social rewards, the disruption of daily social routines, changes in the demeanor and behavior of significant others, forced exclusion from significant family activities, increased interference and social thwarting around familiar places associated with comfort and safety, noncontingent rebuffing and snubbing of affection and contact seeking, increased social control and restraint, and entrapment (the dog cannot simply leave the situation) may exert significant depressive or aggression arousing and disorganizing cognitive, emotional, physiological effects, depending on individual differences expressed by the dogs treated with the social deprivation procedure. Although the procedure may temporarily reduce reactive aggression in some cases via increased anxiety and depressive inhibitory effects (m-type dogs), relatively fearless dogs with low-to-medium anger thresholds and intolerance for frustration (c-type dogs) may be more adversely affected by such stressful household changes.

As emphasized previously, the vast majority of intrafamilial aggressors appear to be socially incompetent and anxious dogs exhibiting a reactive coping style and ISS acquired in association with social interaction failing to support a secure and trusting bond. Social interaction lacking orderliness and consistency is productive of varying levels of anxiety, frustration, and conflict (see *Neurosis and Conflict* in Volume 1, Chapter 9). Instead of relating to family members in a proactive and adaptive way in anticipation of reward conducive to comfort and safety, the dog may become progressively vigilant for signals of punishment (loss of comfort and safety) and reactive. In addition to reducing the dog's ability to form a secure bond with family members, poorly organized interactive reward and punishment may disrupt the dog's ability to organize optimistic expectancies and active modal strategies needed to produce cortical rewards (positive prediction error). As a result, such dogs may exhibit a negative cognitive bias toward interaction with family members, appearing to expect the worst to occur as the result of social contact. These dogs appear on guard and vigilant for signals of punishment (anticipatory anxiety), often exhibiting an extreme intolerance for frustration or discomfort, and a heightened readiness to cope reactively by threatening (conflict) or attacking the owner in response to relatively innocuous social intrusion and interference.

In other cases, the social environment may be relatively orderly, but the dog may not be able to properly experience it as such. Many domestic aggressors appear to view the success or failure of their interaction with family members as something determined by external causes that are largely outside of their voluntary initiative to control. To borrow Rot-

ter's terminology (Rotter, 1966), *externals* place the locus of control over events critical for their comfort and safety beyond their ability to produce or avoid them (see *Locus of Control and Self-efficacy* in Volume 2, Chapter 9). For example, overly dependent dogs may come to view rewarding interaction with family members as something that happens to them rather than something that they make happen for themselves as the result of cooperating successfully with others. As a result of acquired incompetence, such dogs may lack confidence and show high levels of social anxiety in situations that require independent initiative and choice. Externals tend to react to situations rather than adapt to them, and they may not learn very much of benefit from the consequences produced by their reactions. When exposed to increasing pressure, they tend toward extremes of increased motor impulsivity (c type) or immobility (m type). Such dogs may exhibit a number of serious aggression problems, the nature of which depends on reactive (anger and fear) thresholds and allostatic load. Reactive aggressors often show signs of an insecure attachment (neediness), often forming an overly exclusive attachment with a particular family member with whom they may feel relatively comfortable and safe or ambivalent but not aggressive. Such dogs are often diagnosed as dominance aggressors, but are probably better understood as socially incompetent aggressors operating under the influence of a reactive coping style and ISS (see *C-type and M-type Affinity for the Flight-Fight System*). Instead of viewing family members as sources of calming affiliation and reward, such dogs may experience social interaction as intrinsically stressful and productive of anticipatory anxiety and aversion (resentment). Such dogs may show significant conflict with regard to affectionate interactions, appearing to invite contact, but then turn and bite hard without provocation. The dog may allow a family member to pet its head or to rub its belly before the dog unexpectedly delivers a hard bite. Even during affectionate episodes of kissing, dogs have delivered severe and disfiguring bites to the face of loving victims. These dogs may become progressively intolerant toward social contact, especially in certain areas (site-dependent attacks) associated with comfort and safety. When disturbed while in these locations, such aggressors may react to slightest interference as a provocative cost or threat to their island of security.

Canine polymorphic variations affecting anger and fear thresholds, ontogenetic adversity (e.g., prenatal and postnatal stress), problematic socialization and training, and a compromised capacity to experience reward may predispose dogs to acquire an ISS and exhibit aggression toward family members. However, the incompetent intrafamilial aggressor rarely develops without the abetment of an inexperienced or inept leader, lacking the necessary dog savvy, skill, or desire to properly socialize and guide the predisposed dog toward social competence and independence. Pushed to extremis by interactive conflict, mishandling, and entrapment, such dogs may become progressively insecure, reactive, and dangerous. Instead of punishing and further agitating the household aggressor with stressful deprivation procedures that will only serve to further externalize the locus of control, increase the dog's dependency, and perpetuate its incompetence, an opposite strategy is typically adopted whereby contingent reward opportunities are hugely increased in the process of organizing mutually gratifying and bond-enhancing interactions between the dog and family members. The goal of such training is to organize a proactive or adaptive coping style and to encourage interaction conducive to a friendly and cooperative VSS. According to this perspective, building a mutually rewarding and trusting relationship between family members and the dog is the best way to forestall intrafamilial aggression. An important step toward this goal is teaching the dog *how to competently operate family members* to produce somatic and cortical rewards, that is, helping the dog to internalize the locus of control over rewards and to patiently enhance its self-efficacy and mastery by means of cynopraxic training. In an important sense, the goal of such training is to increase the dog's competence, confidence, and independence, that is, to train it to

become more dominant, relaxed, and effective with respect to the gratification of its needs.

In the process of organizing an adaptive coping style, an opioid-oxytocinergic antistress system may be activated to further support bond-enhancing neurobiological and physiological changes incompatible with aggression and anxiety. In addition to increasing affectionate interaction and reward availability, a quality-of-life assessment is performed to optimize exercise, playful interaction, household liberty, and so forth. Interactive conflict and tensions are traced to their sources and converted by means of ICT into situations of potential reward, providing a foundation for mutual appreciation and interactive harmony. A spirit of tolerance, fairness, and optimism should permeate the cynopraxic therapy process, with family members and the dog gradually *joining up* to interact more competently and confidently toward one another in accord with an emergent adaptive coping style, affectionate and playful dynamic modal relations, and the integration of harmonic social relations and roles via a VSS. Instead of perpetuating a heightened vigilance (anticipatory anxiety) for signals of punishment and a readiness for aggressive confrontation, cynopraxic therapy aims to increase the dog's alertness and preparedness for signals of reward by increasing leadership and interaction leading to enhanced comfort, safety, and relaxation (somatic reward) and better-than-expected outcomes (cortical rewards) in association with cooperative transactions. The integration of positive prediction error and surprise teaches the dog to anticipate something positive from the unexpected rather than bracing with anticipatory anxiety for something negative to occur. The cortical reward associated with positive prediction error appears to play a critical role in reorganizing prediction-control expectancies and modifying executive control over aggressive impulses. In general, rather than attempting to suppress aggression by means of physical or psychological domination tactics, the cynopraxic therapy process is carried out in conformity with the dead-dog rule and is oriented toward forming a playful and friendly bond based on mutual trust, affection, and joy.

Limit-setting Actions, Basic Training, and Friendly Cooperation

Organizing functional boundaries between owners and aggressive dogs is based on setting social limits and systematically structuring rule-based interaction through ICT. Although the value of basic training for preventing aggression problems has been questioned (Voith et al., 1992), many authors have noted a beneficial effect on both the incidence of behavior problems and the quality of the human-dog bond following basic training (Blackshaw, 1991; Clark and Boyer, 1993; Jagoe and Serpell, 1996; Goodloe and Borchelt, 1998) (see *Role of Integrated Compliance and Obedience Training* in Volume 2, Chapter 6). Whether obedience training exerts a preventive benefit probably depends on the quality of the training provided and the reliability of the control established, with the dog's ability to follow commands being negatively correlated with the occurrence of behavior problems (Kobelt et al., 2003). Training the dog to defer to social limits and obey promotes a cooperative attitude conducive to effective communication and friendly social interaction. Most dogs exhibiting aggression problems benefit from the introduction of reward-based basic training and the shaping of cooperative behavior. It is not enough to explain to an owner what to do, but, more importantly, the owner must be shown how to do it. Establishing dominance is not just about setting limits, but rather, as J. H. Woolpy (1968) has well stated, "some as yet poorly understood personality factor seems to have the greatest sway" (46). Accomplished trainers not only instruct owners on procedural details, they personify the essential "personality factor" alluded to by Woolpy via subtle and gross body language, vocal expressions, personal presence, and sincerity of purpose. These nonverbal impressions are extremely useful for helping owners to establish an affectionate and healthy interactive relationship based

on social limits, rules, and cooperative expectations. Presence and sincerity of purpose are the hallmarks of master trainers. Basically, such an attitude simply and confidently states without threat or doubt a presence of control. Social dominance is about establishing control, but more than anything else dominance depends on the projection of an attitude characterized by confidence and sincere purpose. Teaching owners how to succeed with their dogs and to avoid aggressive episodes improves their ability to project a confident attitude. Training and behavior-therapy efforts will yield little lasting benefit if the owner remains a victim in attitude toward the dog.

Problems associated with CDA do not emerge spontaneously like a fully armored Athena leaping from the head of Zeus, but gradually becomes serious over time (Takeuchi et al., 2001). CDA problems can often be traced to early ontogenetic influences involving affiliative conflicts. Adult dogs exhibiting domestic-aggression problems were frequently excitable, emotionally reactive, and difficult-to-control puppies (Guy et al., 2001b). Such puppies appear learn at an early age that their owners can be manipulated with threats, sharp teeth, and claws. In addition, puppies at risk are often hyperactive, aggressively possessive (growl and snarl) over food and toys, competitive and reactive to normal discipline, habitually steal and guard forbidden items, resist routine grooming and handling, engage in excessive and persistent mouthing, and may be reactive to physical restraint. Predisposed puppies may react aggressively to being placed into a down position or held there by force, but willingly lie down for a treat. As the result of a failure to establish appropriate limits and social distance (dominant-subordinate relations), the situation may become progressively unstable and rife for serious competitive contests. While this general competitive pattern is common, not all puppies exhibiting the foregoing behavior patterns go on to develop aggressive behavior as adults. Further, in some atypical cases, the aggressive dog may exhibit few or none of the aforementioned early indicators of risk.

Diversion and Interruption versus Punishment

Although punishment (e.g., time-out) can be effective in some situations involving control-related aggression, caution is advised whenever contemplating the use of physical punishment to handle growling and other threat displays. Recommending that a dog owner punish growling is highly questionable and makes little sense in the context of cynopraxic therapy efforts. Low-grade threat displays provide the trainer and others with a margin of safety and warning while interacting with the dog. Suppressing the growl is extremely easy to achieve, but nothing is gained by the effort since it is unlikely to alter the dog's motivation to bite in a way that fosters behavior incompatible with aggression. In managing aggressive dogs, threat behavior should be reduced by means of positive behavioral and emotional changes taking place as the result of establishing an adaptive coping style and reward-based training. The absence of threat displays should indicate the absence of aggressive arousal and intent, not the development of a far more dangerous situation in which the dog remains aggressively aroused but has learned to inhibit threat displays without reducing its propensity to bite (see Species-typical Defensive and Offensive Aggression). Consequently, instead of punishing the growling response, a better approach is to acknowledge the threat by moving away or by evoking a diversionary establishing operation aimed at encouraging behavior incompatible with aggression (see Establishing Operations in Chapter 1). The dog can be diverted from aggressive arousal by various means, including picking up a toy, going to a door and acting like a walk is in the offing, or tossing a treat, with the goal of evoking submissive seeking behavior for the activity or resource. The procedure follows the principle that active submission is established by evoking an appetitive- or social-seeking response that is subsequently rewarded in exchange for cooperative behavior and voluntary subordination (affectionate submission). Directly punishing threatening behavior is prone to produce aggressive reprisal or result in involuntary subordination with resentment and fear.

Moving away from the dog may reinforce the growling behavior, not an entirely desirable outcome, but one far better than suppressing it. Dogs encouraged to growl and threaten are probably at a reduced risk of biting without warning and, having learned that growling works with minimal risk of retaliation, such dogs may be more inclined to limit their aggressive control efforts to such threat displays rather than escalating to overt attacks when they become aroused. The second method (changing the motivational state) typically involves throwing the growling dog a highly prized food item, causing it to shift from a threat-producing mode to food-seeking mode. As the dog's attention turns to the food, it is more likely subsequently to offer behaviors incompatible with aggression, especially in cases where compliant behavior has been reinforced with food in the past. Habitually walking away from a growling dog to get some treats (situation change) and coming back to throw the dog a treat (motivational change) may help significantly to diffuse aggressive tensions associated with that specific trigger situation, especially if the dog is caused to beg and perform a simple exercise or two to obtain subsequent treats. In some cases, merely having the dog repeatedly orient to the sound of a squeaker or smooch followed by a click and the presentation of food can help to shift the dog rapidly from a threatening to a cooperative mode of interaction. The foregoing technique is most effective following several days of intensive preliminary attention training with sit, sit-stay, following, and recall training.

In contrast to the reinforcement that may follow if the trainer walks away from a growling dog, there is little likelihood of inadvertent reinforcement of aggressive behavior occurring as the result of giving the dog food as a diverter at such times, especially if rewards subsequent to the initial presentation (diversionary establishing operation) are made contingent on behavior incompatible with aggressive threats (orienting response, sit-stay, come, and so forth) (see *Interrupting Behavior* and *Diverters and Disrupters* in Chapter 1). Since the goal of threat behavior is the imposition of social or physical space between the owner and dog—not the acquisition of food—the introduction of food at such times is rather irrelevant with respect to the immediate goals of growling; however, in the unlikely event that the dog learns to growl as a way to get food, such growling is of an entirely different motivational significance and order. In such cases, growling for food is an innocuous trick performed under the influence of appetitive incentives and seeking behavior, which signifies something quite different from the growl advertising an imminent threat of overt attack. The appetitive activation of the seeking system appears to exert a potent inhibitory effect on the emotional command circuits mediating the expression of aggression (see *Drive Systems, Aggression, and Behavior Problems* in Chapter 6). In addition to tossing the dog a treat, a diversionary odor that has been previously conditioned with food or play (e.g., a scented squeaker or ball) or relaxation can be introduced at such times as a means to divert the dog's attention and to modulate aggressive arousal. A squeaker containing a wad of orange-scented cotton can be highly effective as a diversionary stimulus, especially if it has been previously conditioned and used as an orienting stimulus in the context of attention training.

Anger, Restraint, and Frustration

Aggressive behavior is intimately associated with emotional antecedents that prepare dogs for aggressive action, especially anger and rage. Anger can be elicited by painful stimulation and physical restraint, but it is also associated with the anticipated loss of valued objects or activities via frustration (Dollard et al., 1939; Berkowitz, 1989). Dogs exhibit varying degrees of tolerance for pain and restraint, with the vast majority of well-socialized and habituated dogs appearing to cope extraordinarily well with mild pain and physical restraint, and rarely showing aggression in response to such stimulation except under circumstances of extreme duress and discomfort. However, some dogs are highly reactive to pain or the threat of painful stimulation, exhibiting

a low threshold for discomfort and restraint. Under the influence of minimal restraint or discomfort, such dogs may struggle violently and attempt to bite in an effort break free. The way dogs respond to restraint and other forms of aversive stimulation depends on genetic and acquired influences affecting behavioral thresholds (Scott and Charles, 1954).

Prominent emotions associated with pain and restraint (loss of freedom) include fear, irritability, frustration, and anger. When pain and restraint are simultaneously produced, escalating fear and anger may be elicited and coalesce into a state of panic and rage, building dramatically and violently until the animal either breaks free or is exhausted. If biting and clawing are successful as the result of such struggle, such behavior will be more likely to occur under similar circumstances of painful restraint in the future. In addition, signals of punishment anticipating painful stimulation and restraint may become conditioned elicitors of fear and anger, resulting in preemptive efforts aimed at avoiding such stimulation. The simultaneous elicitation of conditioned fear and anger by the same social object that otherwise is associated with affiliative comfort and safety may represent a significant source of emotional conflict and anxiety. This general scenario is common in cases involving interactive punishment and reactive aggression.

Repeated exposure to restraint and inescapable aversive stimulation is highly stressful and productive of behavioral disturbance (see *Liddell: The Cornell Experiments* in Volume 1, Chapter 9). In addition, frustration associated with restraint (thwarting the freedom reflex) and loss of control over aversive or attractive events may activate anger/rage circuits. The function of anger is to motivationally intensify defensive behavior, preparing dogs to respond with aggression, if necessary, to successfully prevent the loss of some resource or to control (avoid or escape) an aversive event. As such, anger is adaptive and useful for controlling adverse environments. The evaluation of success and failure with regard to the control of attractive and aversive events entails the existence of significant cognitive processing, whereby the expected outcomes of actions can be compared with what actually occurs. Assessing outcomes and adjusting behavior to fit those assessments takes place at an executive level of organization, probably localized in the prefrontal cortex. The prefrontal area performs a variety of attention and impulse-control functions, modulating the expression of emotional behavior and mediating organized social behavior and learning. Prefrontal deficits are associated with a persistent failure to organize behavior appropriately in accordance with consequences. Under conditions resulting in the stressful habituation of the orienting and attending response (e.g., unpredictable and uncontrollable stimulation) (see *Locus of Neurotogenesis* in Volume 1, Chapter 9), a dog's ability to appraise behavioral output and organize behavior in an adaptive manner may be significantly disturbed. Actions associated with prefrontal disturbances are characterized by hyperactivity, impulsiveness, and immediate gratification. Prefrontal deficits may predispose dogs to exhibit intolerance for frustration and restraint and a resistance to inhibitory training, as well as showing an increased tendency to react to such stimulation with impulsive adjustments, including aggression.

Since the prefrontal area is highly sensitive to stress and prone to disturbances associated with stress, therapeutic efforts in such cases should involves steps to normalize function by reducing sources of environmental and social stress. In addition, various activities enhancing the dog's ability to cope with stress should be introduced and emphasized in advance of the implementation of more intrusive efforts (e.g., withdrawal of social attention). Areas of particular importance in this regard include exercise, play (as safe and appropriate), avoidance of aggression-provoking situations, graduated massage [posture-facilitated relaxation (PFR) training], reward-based training, and the avoidance of provocative punishment. Training a dog to orient and hold its attention on the trainer while performing various basic obedience exercises is a useful way to enhance impulse control and promote organized behavior. Linking the orienting and attending response to the occurrence of highly predictable and

controllable events in association with basic training gradually serves to restore the appraisement and organizing functions of attention. In the case of highly stressed and reactive dogs, selective serotonin-reuptake inhibitors (e.g., fluoxetine or paroxetine) are commonly prescribed, perhaps producing a complementary effect on prefrontal executive normalization when given in conjunction with attention therapy (see *Pharmacological Control of Aggression* in Chapter 6).

Behavior Therapy and Training Procedures

Managing Aggressive Dogs

While the owner is most concerned about eliminating the threat of biting as quickly as possible, the trainer's goal should be to steer the owner's attention toward a better appreciation of the causal factors underlying the dog's biting problem and from there to develop an appropriate program of management, behavior therapy, and training. Effective management involves the introduction of various techniques for reducing adverse environmental stressors and emotional influences. Perhaps the most important goal of management is to teach the owner how to interact safely with the aggressive dog by taking precautions and using appropriate restraint strategies. The sort of management needed depends on the severity and frequency of the aggressive behavior. Dogs with a history of CDA should be kept on a leash whenever around family members at risk. In some cases, a muzzle or halter should be used for added protection, especially in the case of aggressors with a confirmed history of biting. The muzzle or muzzle-clamping halter should be introduced gradually with loads of positive reinforcement to encourage a relaxed acceptance of the restraint. Despite such preliminary efforts, some dogs may never relax while wearing such devices and may exhibit adverse side effects that limit their usefulness (Figure 7.3). The temptation to punish a dog while it is wearing a muzzle or muzzle-clamping halter should be avoided. Such treatment is highly problematic and probably does little or nothing to reduce the risk of aggression when the dog is not so restrained, but may, in fact, make the dog more apprehensive and more determined than ever not to integrate friendly relations with the owner. Punishing a muzzled dog is contrary to the trust-building objectives of cynopraxic therapy and should be avoided. Instead of using the advantage of muzzling to punish the dog, the goal of such restraint is to enable to owner to safely interact in close quarters with the dog without risking an attack. Such restraint provides response prevention, thereby showing the dog that its aggressive behavior is not necessary. Every effort should be made to make the dog feel safe while it is muzzled or wearing a head halter. In some cases, aggressive dogs should be crate trained and learn to accept confinement in other places, as well, without making a disturbance (e.g., confinement in a locked bedroom when guests visit). All interaction with people should be carefully supervised, and persons at risk of making contact with the dog should be warned of the dog's propensity to bite. All social interaction should be managed and structured to promote safe and friendly exchanges. The control of CDA stresses training efforts designed to minimize the risk of an attack while improving human and dog social communication skills, increasing affection and playfulness, and enhancing the dog's willingness to defer and trust family members.

A detailed inventory should be compiled listing all situations in which the dog has either threatened to bite or has actually bitten. The owner is instructed to avoid these circumstances or any other provocative interaction that might lead to aggression. In addition to profiling past aggressive events, the owner should be encouraged to keep a daily journal keeping track of training activities and noting progress or setbacks. Threatening behavior or overt attempts to bite should be recorded with reference to the time, location, and the provoking situation precipitating the aggressive incident (Figure 7.4).

Social Withdrawal, Deprivation, and Cold Shouldering

Preliminary training efforts should focus on adjusting social polarity (see *Reversing Social*

Polarity and Establishing Leadership in Volume 2, Chapter 8), so that the owner becomes the object of increased attention and affection, with the goal of inspiring increased social cooperation and leadership. The owner should encourage the dog to seek attention, affection, and a variety of other rewards by making such things contingent on cooperative behaviors (sit, stand, down, come, stay, wait, and so forth) integrated into everyday activities. Some authorities recommend that a period of social deprivation and cold shouldering should precede NILIF training in order to enhance the dog's interest in social contact and motivation to seek owner affection. The necessity of such a deprivation procedure has not been clearly demonstrated; nonetheless, many anecdotal reports suggest that cold shouldering may pique a dog's interest in social contact and may be useful in some cases not otherwise responsive to reward-based training efforts. If a deprivation procedure is selected, the least amount of deprivation necessary to establish enhanced contact seeking should be used. A significant effect may be produced by as little as a half-day of cold shouldering to prompt a reorientation toward the owner. Typically, the direction of social polarity can be shifted by simply placing access to food, play, or petting on a contingent basis, that is, making the dog beg and work for it. Social deprivation procedures should be considered only in the case of dogs that do not show an active seeking response or willingness to work for the reward. The necessity of more lengthy periods of social deprivation and cold shouldering is questionable and should be avoided, at least until other less intrusive procedures have been tried without success.

Of course, in the case of dogs showing contact aversion with aggressive reactivity, petting and handling may be problematic (see *Contact Aversion and Aggression* in Volume 2, Chapter 8) and should be avoided, at least until progress is made that permits such interaction. In such cases, a brief withdrawal of petting and other forms of gratuitous affection may be beneficial as a starting point. However, the lengthy discontinuation of social contact and comfort giving functions as punishment and may serve only to introduce another element of stress into situation, perhaps making matters worse as a result. Petting and massage provide potential benefits by inducing relaxation and increased feelings of comfort and safety—emotional states incompatible with fear and aggression (see *Taction*

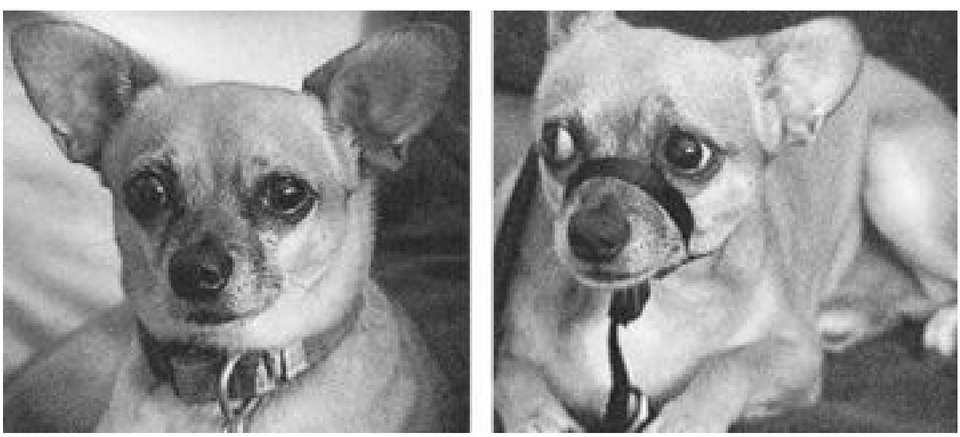

FIG. 7.3. Although most dogs eventually learn to accept halter or muzzle restraint by means of patient exposure and rewards, some may persistently react with an appearance of distress. In the case of this Chihuahua, his demeanor immediately and persistently changed as soon as the halter was fastened and thereafter he lost his appetite for treats, a side effect that severely limited counterconditioning efforts. The dog also refused to eliminate outdoors while walked on the halter, resulting in a brief house-training problem that was immediately resolve by again walking the dog on a leash and collar.

and Posture-facilitated Relaxation in Chapter 6). Finally, in addition to lacking scientific justification, the lengthy withdrawal of social contact is highly intrusive and may violate the LIMA principle (see *Compliance* in Volume 2, Chapter 2). Asking a family to arbitrarily withdraw social attention and affection from a dog for long periods (e.g., 2 to 4 weeks) is a recommendation that is not likely to receive a high level of support and compliance. Abruptly withdrawing affection, play, and other forms of friendly interaction from the dog for weeks at a time is a punitive and stressful measure that may only serve to intensify interactive conflict and tensions between the dog and family members. Instead of ask-

ing the owner to withdraw affection and playful interaction from the dog, emphasis is better placed on helping the owner to discover ways to safely integrate affectionate and playful relations between the dog and family members in the process of building a trust-based bond incompatible with aggression (see *Integrated Compliance Training*). While short-term withdrawal of attention and affection may enhance the dog's willingness to beg for social rewards, there is little reason to assume that longer periods of social deprivation will produce a better effect. The benefits of social deprivation appear to be dose dependent, with relatively brief periods of social deprivation (e.g., time-out) enhancing submissive seeking and de-arousal, while longer periods of social deprivation and isolation may produce emotional withdrawal and depression. To my knowledge, no available scientific evidence supports the notion that long-term social withdrawal and tactile deprivation produces any benefit with respect to the reduction of CDA. However, some evidence does suggest that excessive social deprivation and cold shouldering may produce an adverse effect. For example, animals experimentally exposed to tactile deprivation tend to become more aggressively reactive when social contact with conspecifics is restored (see *Posture-facilitated Relaxation Training*).

Attention Therapy and Submissive Following Behavior

A less intrusive method that appears to be useful and more willingly adopted by owners involves an opposite strategy. Many dogs with a history of aggression may be already under the influence of a long period of social withdrawal and reduced affectionate interaction with the family. Social deprivation may naturally follow in the wake of CDA, as family members avoid making risky contact with the dog or withdraw affection from it as the result of a loss of trust, perhaps causing the problem to worsen over time. Instead of further adding to the dog's loss of social contact and other sources of reward, positive social interaction is deliberately intensified by increasing safe, affectionate, and rewarding interaction between the dog and family members. The combination of somatic (comfort and safety) and cortical rewards (surprise) appears to promote an antistress response conducive to an adaptive coping style. Different types of appetitive and social rewards and toys are given to the dog in exchange for little more than orienting, approaching, following, attending, and waiting, that is, engaging in submissive modal activities.

Many dogs exhibiting increased aggressive reactivity may show evidence of attentional and impulse-control deficits. Such dogs may fail to *connect* or integrate an attentive orientation toward social signals, but may instead appear to actively ignore or resist efforts to establish an attentive interface. The dog may not be entirely oblivious to the trainer or unaware of important aspects of significance with respect to the signals given, but rather seem to respond to social signals in a rather narrow and parochial manner with respect to the more subtle cognitive and emotional significance of social communication. Since many aggression problems appear to involve a chronic failure between the dog and family members to competently communicate and adjust in ways that maintain a friendly field of social exchange, it is critical that a process of training aimed at improving cognitive and emotional regulation be initiated. The dog's ability to socially engage and connect with family members may be impeded by a state of anticipatory vigilance and heightened readiness to engage certain family members as threats, possibly stemming from a history of interactive conflict and disorder, mutual incompetence, or stress-related sensitization of FFS pathways. Whatever the original causes of social anxiety and frustration, the symptoms are treated by similar means involving highly predictable and controllable reward-based ICT. The goal of such training is to promote social competence, relaxation, and to reduce interactive conflict systematically. The enhanced comfort and safety produced by such training are incompatible with frustrative readiness and anticipatory anxiety. Further, the increasing competence and confidence associated with instrumental training promote relaxation and an increasing willing-

ness to experiment and take risks toward the production of adaptive prediction error.

With the emergence of active-submission behavior (e.g., food, play, and affection seeking), a series of simple reward contingencies can be introduced to develop prediction-control expectancies and calibrated emotional establishing operations conducive to positive prediction error and surprise. For example, just as the dog orients in response to a squeaker or a smooch sound, the targeting arc is bridged with a click sound followed by a flick of a closed right hand (see *Target-arc Training* in Chapter 3). A vocal bridge is delivered just as the dog approaches the hand, and a reward is delivered by opening the hand. When taking food, the dog is discouraged from jumping up or grabbing at the food too forcefully. As the dog learns to orient to the sound of a squeaker, its name can be presented just in advance of the squeaker sound. The type and size of rewards are varied and presented in a manner that is conducive to positive prediction error and surprise (see *Prediction and Control Expectancies* in Chapter 1). A scented squeaker can also be used as an orienting stimulus or a conditioned diverter. In addition to orienting and bridge conditioning, preliminary training should include training the dog to make and hold friendly eye contact. With the dog standing or sitting, the trainer calls the dog's name or makes a smooch sound, followed by a bridge ("Good" or click) and the delivery of a food reward (see *Introductory Lessons* in Chapter 1). Training the dog to orient and hold sustained eye contact enhances the dog's ability to discriminate the trainer's actions and intent accurately and competently, thereby improving social communication and reducing the risk of aggression due to reactive adjustments. Squeakers can be placed on treat boxes and kept with leashes, toys, and other sources of attractive stimulation. The owner is instructed to sound the squeaker when coming into the house, especially at homecomings after a lengthy absence. The stimulus change is aimed at intensifying affectionate and appetitive attraction, precisely the opposite of the cold-shoulder procedure as described previously. The goal of these preliminary attention and orienting procedures is to make the owner a source of focused attention and following behavior.

When taking food, the dog is discouraged from jumping up and encouraged to take the treat gently. Initial lessons should focus on training the dog to come from various place in the home. The squeaker can be used to get the dog's attention, followed by the word "Come" as the dog turns toward the trainer. The dog is rewarded upon coming and immediately released with "OK" and a clap. Once the dog learns to orient to the sound of squeaker, its name can be presented just in advance of the squeaker sound. After the dog has learned to come reliably, it is encouraged to follow along at the trainer's left side and is immediately rewarded as it approaches. Every few steps, the trainer rewards the dog so long as the dog remains close by on the left side. If the dog becomes distracted and moves away, the squeaker is squeezed and the orienting response is bridged with the clicker, as the trainer turns away from the dog and encourages the dog to follow along with friendly smacking, smooching, and sweet talking, whereupon it is rewarded by saying "Good," and the food reward is delivered from a closed hand. With the presentation of most food rewards, the dog is petted under the chin and other locations producing an affectionate response. Once the dog is coming and following the trainer, a sit response is introduced. With the dog following at the left side, the trainer clicks, stops, and waives the right hand over the dog's head. As the dog sits, the trainer says "Good" and rewards the sit action as it is completed. After staying for a brief period, the dog is rewarded again and periodically thereafter on a variable-duration schedule, but must continue sitting until it is released with an "OK" and clap signal. During the sit-stay, the dog should be encouraged to make and maintain eye contact with the trainer, especially at the beginning and at the end of the exercise. As the dog's abilities improve, variations are introduced and practiced with the purpose of increasing attention and impulse-control abilities. Voith's (1977) sit-stay program provides a systematic way of developing sit-stay and impulse-control abili-

ties conducive to attention-therapy objectives (see Appendix A).

Integrated Compliance Training

The vast majority of domestic dog bites signify the presence of reactive incompetence in association with an ISS and a failure of the dog to integrate harmonious and trusting relations with family members. Restoring a trust-based bond incompatible with aggression depends on competence-enhancing ICT and the formation of affectionate and playful dynamic modal relations. An important function of ICT is to establish orderly cooperative relations between the dog and family members in association with everyday activities and sources of potential interactive conflict.

A significant aspect of social competency includes training the dog how to obtain and perpetuate gratifying experiences without resorting to aggression. In addition to relinquishing control over resting areas and possessions, the dog should learn when access to such things is permitted and how to go about getting such access. Similarly, the dog should learn to wait and make eye contact before entering or leaving the house. Social nuisances (e.g., barking and jumping up) can be brought under the control of vocal and gestural signals and then appropriately prompted and rewarded or discouraged as required by the particular situation. For example, during homecomings, the dog can learn to wait before being invited to jump up to say hello. Pawing dogs can be trained to give a paw on signal while pawing at other times is discouraged by the loss of reward. Rather than forbidding behavior, generally the best strategy is define occasions when such behavior is acceptable and productive of reward. Rather than reflecting dominance-related incentives, CDA most often involves a persistent failure of dogs to regulate aggressive impulses competently in the presence of social actions portending a loss of comfort or safety. Most dogs exhibiting domestic-aggression problems do not appear to be competing for rank or privileges of status, but are simply exhibiting socially inept and reactive behavior under the influence of autoprotective incentives. Aggression in such cases appears to stem from a history of inappropriate or inadequate owner control efforts and a failure to integrate friendly and playful dynamic modal relations and roles into a VSS for obtaining reward and avoiding punishment. According to the involuntary subordination hypothesis, reactive domestic aggression is prone to develop in the context of persistent interactive conflict and tensions, whereby interaction with the owner sensitizes the dog to social signals of punishment (loss of reward and nonreward).

Interactive conflict and tensions (intolerance and irritability) emerge in the context of antagonistic control incentives converging on points of common interest. Instead of the owner taking ownership of the resource and providing the dog access to it in accordance with a rule-based contingency promoting compromise and cooperation (VSS), the owner may interfere or compete with the dog by punishing reward-seeking activity or by preventing the dog from obtaining gratification (comfort and safety); that is, the owner comes between the dog and reward or physically denies the dog access to it, but without leading the dog to obtain the reward in a cooperative way. In such cases, ICT can be extremely useful for establishing a rule-based pattern of social interaction promoting enhanced cooperation and trust (see *Benefits of Cynopraxic Training* in Chapter 1). Sources of agitating interactive conflict are identified and objectified as potential sources of reward for mediating mutual appreciation and interactive harmony. Conflict is resolved by enhancing the owner's ability to take ownership of rewarding resources and to exert competent control by means of limit-setting actions and reward-based training, whereby subordinate compromise and cooperation are rewarded by access to previously barred activities and objects of reward. By such means, a VSS is mediated with the dog becoming progressively sensitive and alert for signals of social and appetitive reward while at the same time helping to mobilize oxytocinergic antistress and calming effects associated with the flirt-and-forbear coping style (see *Oxytocin-opioidergic Hypothesis* in Chapter 6). Instead of punishing aggressive tendencies, training is

dedicated to instilling a heightened sense of trust and confidence in the owner as leader and friend. Emergent mutual competency and confidence between the dog and the owner naturally result in increased behavioral flexibility and relaxation. Rule-based social interaction facilitates cooperative behavior and prediction-control expectancies incompatible with reactive irritability and intolerance, educating the dog to form an affectionate, cooperative, and trusting orientation with respect to family members.

The effectiveness of ICT is enhanced when performed in conjunction with other training and therapy procedures. In addition to learning how to acquire rewards under an owner's control, a dog needs to learn how to cope with everyday provocative challenges via graduated exposure to directive control. Such training helps to restore a dog's sense of safety and control. By means of complementary behavior-therapy procedures, including graduated directive control and punishment (TO), nonprovocative restraint and taction therapy (PFR training), and avoidance training when appropriate, a dog in stages learns that it can control rewarding situations as well as provocative or mildly threatening ones without losing trust and resorting to aggression. In addition, behavior that is successfully brought under the control of appetitive and social rewards and avoidance training is steadily integrated and brought under the influence of ludic incentives by means of play training. Play antagonizes the emotional irritability and rigidity commonly present in dogs exhibiting CDA. Play is particularly valuable for integrating dynamic modal relations and promoting interactive harmony, tolerance, and trust. The success of an aggression-therapy program is based on the shaping of overt behavior incompatible with aggression, giving evidence of at least three areas of improvement: increased composure (competence and confidence), relaxation, and playfulness. Since aggressive threats may be rapidly suppressed by means of punishment, but without necessarily reducing the risk of overt aggression, the mere absence of aggression is not a useful measure of improvement. Evaluations based solely on the absence of aggression violate the dead-dog rule (see *Dead-dog Rule* in Volume 2, Chapter 2). Ultimately, the goal of dog behavior therapy, as well as preventive training, is to reduce the risk of CDA by taking appropriate safety precautions and promoting a more playful and trusting bond between the dog and family members.

Counterconditioning

Previously conditioned aversive and appetitive stimuli are subject to a variety of modifying influences, including extinction and counterconditioning. For example, if an conditioned stimulus (CS) is repeatedly presented independently of an unconditioned stimulus (US), the conditioned association between the CS and US will gradually degrade or extinguish, but it will not be permanently uncoupled. Contrary to a popular belief, extinction does not erase past learning. As a behavior-therapy procedure, extinction is notoriously inefficient and subject to "savings" that make its use problematic in the treatment of behavior problems (see *Spontaneous Recovery and Other Sources of Relapse* in Volume 1, Chapter 6). Counterconditioning provides a more effective and reliable means for altering conditioned aversive associations than punishment and extinction. Rather than passively discontinuing the contingency between the CS and US, counterconditioning actively establishes a new contingency and expectancy between the eliciting stimulus and the emotional arousal elicited by it. This change is produced by arranging the fear- or anger-eliciting stimulus to occur in close association with the elicitation of a stronger and incompatible response that overshadows and antagonizes aversive arousal.

Counterconditioning has many applications in dog training and behavior therapy, but is especially useful in cases involving problem behavior operating under the influence of specific conditioned aversive stimuli and evoking contexts (see *Counterconditioning* in Chapter 3). The process is based on the antagonizing effects that responses of opposite emotional and hedonic significance have on one another:

1. If two emotional responses of opposite motivational and hedonic significance are elicited at the same time, the stronger response will tend to overshadow and antagonize the weaker one.
2. If both emotional responses are of approximately equal strength, they will antagonize each other and produce varying degrees of emotional conflict.
3. If an aversive response is stronger than the antagonizing response, the latter will fail to restrain the former and may instead become associatively linked to it.

The risk of producing emotional conflict and stress or conditioning the antagonizing stimulus to elicit rather than restrain the aversive response underscores the importance of gradual exposure when applying a counterconditioning procedure and performing counterconditioning in conjunction with appropriate precautions and response-prevention procedures (see *Fear Reduction and Approach-Avoidance Induction* in Chapter 3). Counterconditioning usually involves the presentation of a series of graduated exposures in which provocative stimuli or situations are repeatedly presented to the dog in a progression of increasing strength and potential for eliciting aversive arousal while the dog is simultaneously presented with a stronger antagonizing stimulus that overshadows or restrains aversive arousal. After repeated trials in which the antagonizing stimulus successfully restrains aversive arousal, the provoking stimulus gradually becomes linked with the antagonizing stimulus and the emotional arousal produced by it. If the antagonizing and provoking responses are of approximately the same magnitude, stressful conflict may ensue adversely affecting counterconditioning efforts.

The provoking stimulus, as the result of newly formed associations with emotional arousal elicited by the antagonizing counterconditioning stimulus, gradually acquires new predictive and emotional associations that are incompatible with its previous significance. The power of counterconditioning to alter the significance of conditioned aversive stimuli makes it highly useful for the treatment of many aggression problems. For example, presenting food (antagonizing stimulus) to a hungry dog that resents reaching and petting actions (provoking stimuli) may gradually alter the dog's response to such activity by the overshadowing effect of appetitive arousal. First tossing food to the dog from a distance, and then through progressive steps giving it to the dog by hand, may help to alter the dog's response to reaching and petting actions via the antagonizing effect of appetitive arousal. Over several trials, the dog may learn to welcome the previously provocative actions, now interpreting them as antecedents associated with getting food. A similar counterconditioning procedure can be used to alter aversive associations linked with being leaned over or stared at and so forth, thereby changing the dog's expectations regarding the significance of such actions. By repeatedly pairing provocative gestures and postures with the presentation of food (tossed to the dog), the dog is provided with new information with which to reinterpret and modify its expectations of such interaction.

The antagonizing effects of counterconditioning on aversive emotional arousal appear to benefit from the additive effects of multiple sources of antagonistic stimulation. Any conditioned or unconditioned stimulus can be used for counterconditioning purposes so long as it is capable of evoking a reliable incompatible emotional response from the dog. The selected stimulus can be used alone or in combination with other similarly effective stimuli. Food is the most commonly used antagonizing stimulus in routine training efforts, but affectionate petting and talking, massage, and play are also often used in combination or separately to antagonize aversive emotional arousal. The potency of food as a counterconditioning stimulus is dependent on the dog's level of hunger and its appetite for the food given to it. Increased appetitive counterconditioning effects can be produced either by increasing the dog's level of hunger or by increasing the appetitive value of the food reward. Although a 12- to 24-hour deprivation period is usually sufficient to pique an increased interest in food, some dogs with

reduced appetites (not uncommon among stressed fearful or aggressive dogs) may require a reduced-calorie diet or medication in order to generate a more conducive level of motivation for appetitive counterconditioning. A significant enhancement of food as a antagonizing stimulus is achieved by varying the type and amount of food given to the dog from trial to trial. Odors that have been previously paired with relaxation induced by massage and PFR training work well in combination with other counterconditioning stimuli. The conditioned odor is delivered on the breath, hands, or body or by other various other unobtrusive means (e.g., squeaker bulb). Conditioned odors appear to help the dog relax, possibly restraining undesirable aversive arousal and thereby rendering the dog more receptive to other counterconditioning effects. The ultimate usefulness of ICT, counterconditioning, and other reward-based training efforts will hinge on the dog's willingness to integrate friendly relations with the target of aggression. Some dogs, despite the most conscientious and dedicated efforts, may continue to show a threatening attitude, remaining intolerant and reactive to the approach of certain family members. The subgroup of domestic aggressors that fail to show signs of integrating friendly and submissive relations in response to reward-based training and counterconditioning efforts, should be removed from the home. During all counterconditioning procedures, the dog should be appropriately restrained on leash, control post, halter, or muzzle, as necessary for safe exposure, handling, and response prevention.

Although counterconditioning appears to have several useful applications in dog training, there have been a number of laboratory studies that have questioned the efficacy of the procedure for modifying fears (see *Critical Evaluations of Counterconditioning* in Chapter 3) and aggression (see *Counterconditioning: Limitations and Precautions* in Chapter 8). Currently, the value of counterconditioning for controlling aggression remains unproven, however, sufficient anecdotal evidence and case reports exist to support the use of counterconditioning as a support tool in the context of canine behavior therapy, but perhaps not as a stand alone classical conditioning procedure. Cynopraxic training theory emphasizes the unity of prediction-control expectancies, emotional establishing operations, and goal-directed action in the process of organizing adaptive behavior, making stand alone counterconditioning unnecessary. In general, the gradual disconfirmation of aggression-provoking expectancies by means of repeated instrumental exchanges around reactive points of conflict that result in mutual reward serves to integrate more competent and cooperative social behavior while naturally altering emotional establishing operations and control incentives in ways that are incompatible with aggression. Whatever benefits might be achieved by countercondtioning in isolation are achieved by cynopraxic training and therapy efforts in the process of shaping more competent prosocial and friendly behavior.

The effects of counterconditioning appear to be particularly problematic and variable in the treatment of impulsive, reactive, and trait aggression (see *Conflicts and Rituals Toward Novel Social Stimuli* in Chapter 8). For example, dogs possessing strong watchdog propensities may be genetically contraprepared to respond to counterconditioning efforts. In the absence of social familiarity and attraction, dogs expressing a rigid watchdog script may be unable to experience outsiders with the sort of trust needed to render food-sharing exchanges as safe–a precondition required to mediate the social benefits of counterconditioning. In addition, dogs expressing unstable temperaments and reactive coping styles may function under a persistent negativity bias for signals of punishment (loss and risk)—a bias that may overshadow and block counterconditioning effects. Counterconditioning may also prove problematical in the case of avoidance-related aggression problems (see *Response Prevention*) or aggression occurring in association with an ISS that has been partially suppressed by physical punishment. In the latter case, as fear is reduced by counterconditioning a transitional point may be reached that significantly increases the risk of aggression (see *Graded Exposure and Response Prevention* in Chapter 3).

Time-out

Although punishment can significantly complicate matters, if used properly and selectively, it can also provide a useful means for controlling certain forms of CDA. The primary function of punishment is to offset or minimize reinforcing consequences produced as the result of aggressive actions. Punitive measures incorporating disruptive startle or momentary social isolation are superior to procedures that depend on manual restraint and physical punishment. Ideally, punitive measures should meet at least two criteria: (1) punishment should not evoke more aggression, and (2) punishment should be motivationally relevant and antagonistic to the goals of aggression. A powerful punitive technique that meets both of these criteria is time-out (TO), which has been shown to suppress avoidance-motivated behavior (Nigro, 1966), competitive excesses in puppies (Polsky, 1989) and aggressive behavior in dogs (Nobbe et al., 1980) (see *Using Time-out to Modify Behavior* in Volume 1, Chapter 8). In addition to promoting rapid de-arousal, the brief period of isolation associated with TO serves to heighten subsequent interest in social contact and other rewards made available during time-in (Figure 7.5).

Besides being effective with minimal risk of side effects, TO avoids the hazards associated with physical punishment. Appropriate restraint and control of the dog is crucial for the effective use of TO. As deemed necessary to ensure safety, an aggressive dog should be kept on leash with a slip collar, halter, or muzzle at all times when it is in contact with people. If the dog lunges or snaps during exposure and counterconditioning efforts, the leash is pulled tight and the dog is rapidly hauled off to a separate room under continuous leash pressure (bridging stimulus). The entire procedure should make the dog experience a dramatic loss of control over the situation as the result of the aggressive action. When pulled forward by the leash, most dogs resist by pulling back, making forward attacks less likely, but such attacks do occur and may necessitate emergency defensive measures to counter. Dogs presenting such a risk should be kept on a muzzle-clamping halter or muzzle and slip collar. Rather than forcing the dog into the TO room or swinging it around, the trainer should enter the TO room (e.g., bedroom) and back out, leaving the dog on the other side. In cases where there is not enough room to turn around easily, the dog can be left outside of the room as the trainer enters and closes the door on the leash. A moment should be taken to make sure that the dog is clear of the door as it is slowly closed and then, when approximately 1 inch from being fully closed, the door is sharply shut for emphasis. The leash should be pinched in the doorjamb approximately 8 inches above the door handle, leaving only enough slack on the other side for the dog to stand or sit but not leaving room for it to move around or lay down. If the dog complains or scratches, the door can be opened a crack and an upward leash prompt can be delivered to discourage the behavior. After 30 to 60 seconds, the trainer should praise the dog as it is released from TO. The dog is immediately returned to the eliciting situation where an incompatible response is prompted and rewarded, thereby setting the stage for more positive and cooperative interaction. In the case of dogs that have received PFR training and olfactory conditioning, the odor used can be diffused into room to help facilitate relaxation and reduce aggressive tensions.

TO can be effectively used to control a variety of attention-seeking and competitive excesses that may also present with an aggression problem (see *Time-out, Response Prevention, and Overcorrection* in Chapter 5). After each TO, the dog is taken back to situation where the misbehavior occurred, and more appropriate behavior is prompted and rewarded. The TO procedure is repeated as needed until the undesirable response is suppressed or weakened sufficiently to allow for effective conditioning of alternative behavior. The suppressive effect of TO is cumulative and most common social excesses respond within three or four repetitions in close succession, given that an alternative behavior is encouraged at the same time. To be maximally effective, TO should be carried out in the context of a reward-dense training environment (see *Time-in Positive Reinforcement* in Volume 1, Chapter 8).

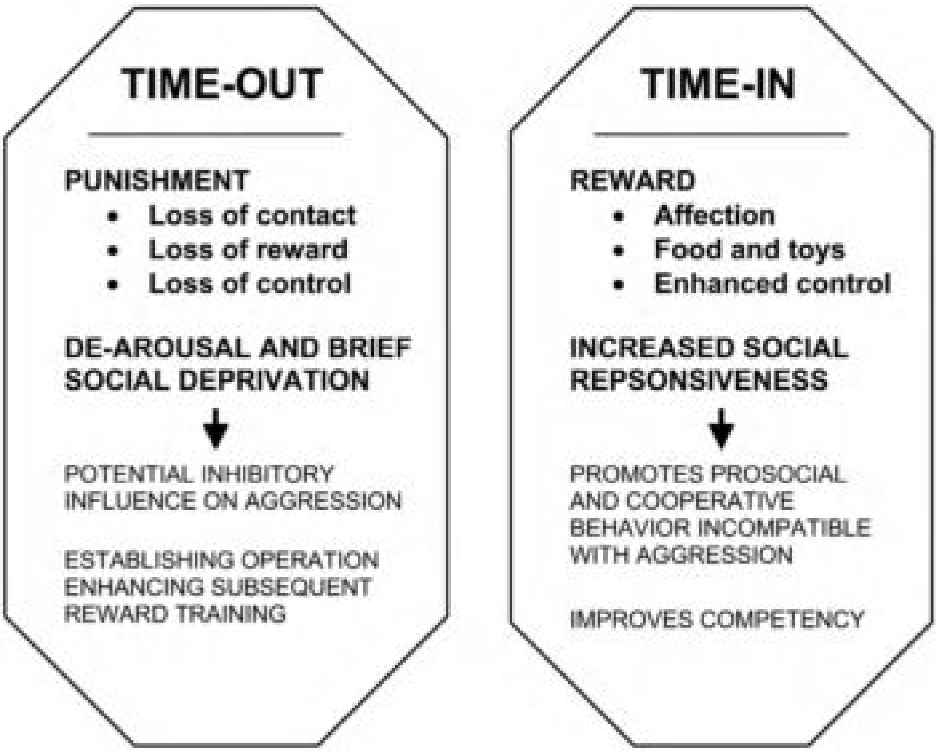

FIG. 7.5. Time-out (TO) is a highly effective punishment technique for the control of some forms of aggressive behavior. TO should be brief and performed within the context of reward-dense time-in (TI) training and counterconditioning efforts. The absence of a reward-dense TI situation significantly reduces the effectiveness and value of TO.

Response Prevention

Since many aggressive dogs appear to threaten or bite as the result of avoidance learning in association with the activation of the FFS, special problems may be encountered that necessitate the use of response-prevention techniques (see *Response Prevention and Directive Training* in Volume 1, Chapter 6, and *Graded Exposure and Response Prevention* in Chapter 3). Aggression operating under the influence of avoidance learning may persist despite conscientious counterconditioning and other positive training efforts. According to the Seligman-Johnston theory (Seligman and Johnston, 1973), once an avoidance response is established, the role of fear is gradually subordinated to reinforcement or extinction effects mediated by the confirmation or disconfirmation of expected outcomes occurring in association with the avoidance response (see *Fear, Cognition, and Avoidance Learning* in Volume 2, Chapter 3). If the avoidance response preempts the aversive event, the controlling avoidance expectancy is confirmed and the response is reinforced, whereas, on the other hand, if the aversive event follows despite the occurrence of the avoidance response, the controlling avoidance expectancy is disconfirmed and the avoidance response is punished and undergoes extinction. The crucial issue here is that fear and its reduction are not directly relevant to the maintenance of a well-established avoidance response. Further, since reinforcement of the avoidance response is based on the preemptive nonoccurrence of the aversive event, the avoidance response may continue long after the aversive threat is removed. Consequently, despite intensive counterconditioning, an

avoidance response may continue intact so long as the controlling expectancy is not disconfirmed or until an incompatible expectancy and response are formed.

There are two ways to disconfirm a faulty avoidance expectancy: (1) arrange for the avoidance response to fail (extinction-punishment), or (2) prevent the avoidance response from occurring in the presence of avoidance discriminative stimuli (response prevention). In the first instance, the aversive event is arranged to occur contingently upon the emission of the avoidance response (punishment), thereby disconfirming the controlling avoidance expectancy. As a result, the dog may experiment with other escape strategies until a response is found that succeeds. Consequently, the successful escape response will take the place of the disconfirmed avoidance response and continue so long as it successfully produces outcomes that confirm the modified avoidance expectancy. Although representing the most common procedure used to control avoidance aggression, the approach is problematic and fraught with risk. Under the influence of physical punishment, avoidance-related aggression may rapidly escalate and become significantly worse as the result of vicious-circle effects. In the second case, the avoidance response is prevented from occurring in the presence of avoidance-signaling discriminative stimuli, thereby compelling the dog to recognize that the avoidance response is no longer necessary. As a result of response prevention, the dog learns that the avoidance signals no longer predict an aversive event and that the avoidance contingency has been discontinued, thereby resulting in the extinction of the avoidance response. During exposure with response prevention, a new significance can be effectively linked with the defunct avoidance signals by means of counterconditioning. If a defunct avoidance signal is repeatedly paired with an attractive event (e.g., food, petting, or play), a new incompatible association and function are produced, whereby the previous avoidance expectancy is not only disconfirmed, but is gradually replaced by an antagonistic approach expectancy.

Similarly, in the case of avoidance-related aggression, a dog may continue to threaten or bite under the influence of a faulty avoidance expectancy, with the character of aggression becoming progressively confident and fearless as the result of a history of successful control, especially if it occurs in the absence of reprisals. The controlling avoidance expectancy may continue to maintain the aggressive response despite intensive counterconditioning and absence of aversive stimulation. The avoidance-related aggressive response is reinforced preemptively, requiring only that the original aversive event not follow the occurrence of an attack—an outcome that would disconfirm the controlling avoidance expectancy. As a result, avoidance-related aggression may continue to occur in the presence of certain social signals that are often benign and innocuous, until the aggressor discovers that the controlling avoidance expectancy is faulty and the aggressive avoidance response is unnecessary and defunct. Under normal circumstances, the avoidance aggressor may not discover that the avoidance contingency is no longer in effect, causing it to threaten or bite in the absence of actual threats and discomfort. By means of response-prevention procedures in which aggression is prevented by various means, including leash and halter restraint, crate confinement, and muzzling, the dog is compelled to learn that the avoidance threat or attack is unnecessary. Exposing a dog to innocuous and mildly provocative social stimuli, while at the same time blocking aggressive responses, gradually causes the dog to recognize that the aggressive response is unnecessary to protect its safety. Response-prevention procedures should be performed in a way that emphasizes safety from aversive stimulation. The presence of attractive and relaxing stimuli and a familiar location may help to reduce adverse emotional arousal associated with restraint and exposure. In addition, a graduated counterconditioning procedure is often used during response prevention in order to link provocative social signals with antagonistic emotional arousal incompatible with aggression, thereby replacing the defunct aggression-avoidance expectancy with an incompatible affiliative-

approach expectancy. In some cases, especially those that are unresponsive to response prevention and graduated counterconditioning, punishment (TO) can be a viable means to disconfirm the controlling avoidance expectancy. Punishment in such cases works to the extent that it causes the aggressive avoidance response to fail while at the same evoking a response incompatible with aggression that permits reinforcement by the owner as a source of safety and comfort. However, inappropriate physical punishment may only cause the dog to fight back more violently under the combined excitatory influences of fear and anger, thereby resulting in a stronger and more dangerous response—a significant risk associated with punishment. Panic-related aggression may, in some cases, result from physical punishment inappropriately applied against avoidance-related aggression, thereby producing a much more dangerous and difficult-to-control problem.

Posture-facilitated Relaxation Training

Evidence of contact aversion and resentment of handling is frequently exhibited by aggressive dogs. Dogs may become averse to such interaction as the result of a history of unwelcome handling in the past (e.g., excessive picking up and hugging) or aversive-traumatic conditioning (e.g., physical punishment or traumatic restraint) (see *Contact Aversion and Aggression* in Volume 2, Chapter 8). Extremes involving too much (agitation) or too little (deprivation) tactile stimulation and handling may result in contact and handling aversion. Petting may be particularly annoying for dogs that lack a trusting bond with their owners. Whatever the cause, it is clear that tactile stimulation exerts a profound influence on a dog's emotional state, with the dog's relative receptivity to petting and other forms of handling reflecting various biogenetic and acquired differences affecting emotional reactivity, social attraction, and propensity for aggression (see *Taction and Posture-facilitated Relaxation* in Chapter 6).

Prescott (1971) has emphasized the role of tactile deprivation as a causative factor predisposing animals to overreact to social tactile stimulation. He has postulated the existence of a somatosensory-cerebellar pathway mediating increased excitability and stimulus-seeking behavior resulting from tactile deprivation. According to Prescott's hypothesis, stress associated with tactile deprivation promotes the development of a variety of emotional and behavioral disorders, including depressive reactions, stereotypies, hyperactivity, hyperexcitability, excessive seeking behavior, habituation disturbances, impaired pain sensitivity, and impulsive aggressive behavior (Prescott, 1971). Cairns (1972) also found that mice tend to become more reactive, irritable, and aggressive as the result of tactile deprivation. He tested this hypothesis by comparing the reactivity of social isolates to different sources of sensory stimulation, finding that isolates were much more emotionally reactive to tactile stimuli than to visual or auditory stimuli. Fuller (1967) found that isolated puppies were less fearful and reactive in an unfamiliar area if they were handled and stroked before and after exposure. Handling appeared to reduce arousal levels and stress-related reactions evoked by the situation. Persons with autism often show an aversion to tactile stimulation, causing them to stiffen, flinch, or attempt to pull away when touched. Autism is an emotionally insular condition of isolation and inability to relate empathetically with others. The autistic aversion to touch contact appears to be ameliorated by massage, an effect that may be facilitated by the highly predictable and rhythmic nature of the process (Field, 1995). Similarly, dogs exhibiting contact aversion toward human touch and handling often show a positive response to massage in the context of PFR training.

A central focus of PFR training is to form positive conditioned associations with handling and restraint via graduated exposure and massage, response prevention, counterconditioning, and the induction of progressive relaxation, with the net effect of antagonizing reactive emotional responses to such contact (see Appendix C). In addition to inducing relaxation, massage with PFR training, when performed in a highly repetitive and stereotypic manner, appears to produce significant benefits in most dogs by reducing stress, by

promoting deference to manual control, and by reliably producing comfort and feelings of safety—behavioral and emotional effects that are highly beneficial in the context of behavior therapy. Nonthreatening manual restraint and postural shifts ranked in terms of a progressive loss of control and submission play an instrumental role in this process of progressive subordination and relaxation (see *Posture, Response Prevention, and Posture-facilitated Relaxation* in Chapter 6). PFR training facilitates a more organized psychophysiological response (parasympathetic dominance) by competing with the reactive and disorganizing influences of sympathetic arousal occurring in association with fear, anger, and frustration.

Dogs with a history of overt aggression should be handled with caution and always kept under appropriate restraint during PFR training. Dogs posing a significant risk of aggression should be leashed and muzzled during PFR training (Figure 7.6). In addition to reducing the risk of attack, the muzzle can provide a salutary response-prevention effect if properly introduced and used. As the risk of aggression is reduced, the level of restraint can be proportionately adjusted to match the risk presented by the dog. The provision of ambient music during PFR training may help to facilitate a relaxation response in some reactive dogs. Wells and colleagues (2002) have reported that classical music appears to exert a calming effect in dogs, as indicated by decreased barking and a greater amount of time spent resting in comparison to controls (no stimulation) living in a kennel environment. Each postural prompt and shift of position is paired with the word "Relax" or "Easy," vocal signals that may be gradually conditioned to predict safe handling and comfort. As the PFR cycle progresses, an olfactory stimulus can be introduced and paired with the deepening relaxation response (see *Olfactory Conditioning* in Chapter 6). After several cycles of PFR training, the odor can be presented at earlier points in the massage sequence, thereby acquiring conditioned properties associated with the induction of relaxation. Gradually, the odor itself can be use to produce a facilitatory effect on the induction and depth of the relaxation response. Certain odors may exert an intrinsic calming effect that may make them more associable with massage-induced relaxation (see *Fear of Loud Noises and Household Sounds* in Chapter 3). For example, chamomile and lavender have been shown to reduce alpha 1 activity in association with subjective reports of increased feelings of comfort (Masago et al., 2000) and stress reduction (Motomura et al., 2001). The conditioned odor can be delivered by a squeaker or by hand or more generally by a mister or a pump diffuser. The conditioned odor is used in conjunction with other behavior-therapy procedures to help manage aversive states and promote relaxation during counterconditioning efforts.

Punishment

Punishment in the case of CDA should be viewed as a damage-limiting option rather than a routine aspect of the behavior-therapy process. Although harsh physical punishment is inappropriate and should be avoided, overt control-related aggression should be countered with disruptive startle or TO whenever possible, but only in situations were the punitive event can be safely performed and is unlikely to cause the dog to escalate aggressive efforts. Such punishment is primarily performed to offset inadvertent reinforcement that may be produced by overt aggression. Despite the risks involved (see *Species-typical Defensive and Offensive Aggression*), a limited use of punishment may be expedient in some cases, but only after basic control is established by means of reward-based training (Line and Voith, 1986). However, instead of focusing too much attention on punishment, the emphasis should be placed on avoiding provocative social interaction that poses a risk of triggering aggressive episodes while at the same time increasing the probability of evoking more friendly behavior. Finally, once reward-based control is established, mild punishment and avoidance training may be useful to further enhance competent coping skills. As the result of effective reward-based training and gradual exposure to inhibitory training, dogs learn how to regulate their responses to mildly provocative stimulation more adaptively and competently—influences that are highly beneficial

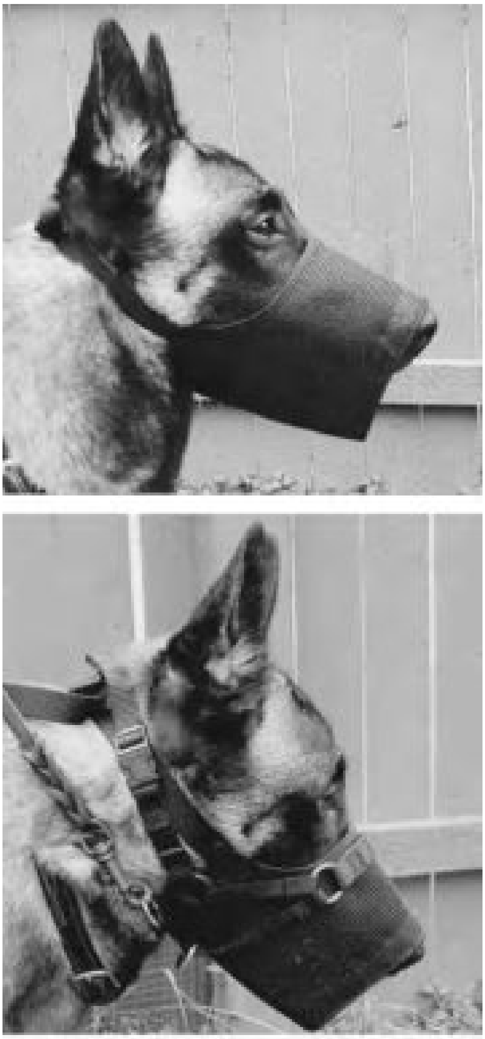

FIG. 7.6. A variety of muzzles are available, but perhaps the most comfortable are those made with a mesh fabric. The muzzle should be introduced gradually in association with highly attractive treats and other positive outcomes. Introducing muzzles too rapidly or roughly may cause dogs to react aggressively or refuse to let themselves be muzzled in the future. Muzzle and halter training requires significant experience and skill to avoid situations that might result in bites to the hands. In situations requiring a high degree of control while limiting the risk of biting, a halter and muzzle can be used in combination.

in the treatment of most forms of domestic aggression.

MANHANDLING AND PHYSICAL PUNISHMENT

Until relatively recent times, harsh physical punishment (e.g., beating) was commonly recommended as a preferred means for controlling aggression and other behavioral excesses (Most, 1910/1955; Lorenz, 1955). Although the measured use of physical force by leash and momentary manual imposition can be useful for enhancing control from time to time, manual methods that intentionally and routinely involve hitting, wrestling, and provocative manhandling directed against aggressive dogs have little (if any) redeeming value for long-term and generalized control of aggression and may make such problems potentially far worse than if nothing had been done at all. Even in cases where such methods succeed in intimidating the aggressor, there is little chance that the inhibition will generalize to other family members who are unable to defend themselves with such physically demanding and skill-dependent punitive actions. In situations where such punishment is used, children may be exposed to an increased risk of attack as the result of punitive agitation, unanticipated behavioral contrast effects (see *Behavioral Contrast and Momentum* in Volume 1, Chapter 7), and redirected attacks. Finally, severe physical punishment may succeed in suppressing threat displays, but without significantly modifying the dog's emotional propensity for aggressive behavior (see *Assessment and Treatment Priorities*). As a result, the roughed-up dog may gradually learn to bite without warning or bite preemptively when threatened by the owner with such treatment. In summary, there are three major problems associated with forceful manhandling and punishment:

- Manhandling places inexperienced dog owners at a significant and unnecessary risk of being bitten.
- Manhandling does little to change the causes of domestic aggression substantially and may actually cause the dog to escalate its aggressive efforts against the owner.
- Manhandling may rapidly suppress threat displays without reducing a dog's propen-

sity to bite, perhaps increasing the dog's aggressive propensity while at the same time making it less predictable and more dangerous.

The use of provocative striking, manhandling, and restraint techniques should be avoided except in the rare case of self-defense and the protection of others, where alternative means of emergency restraint are not available or prove inadequate. Trainers are under a professional obligation to perform training services with dogs under appropriate restraint and to avoid provocative circumstances that necessitate such methods of intimidation for self-defense. Mistakes can happen, and trainers should be skilled in a variety of restraint techniques for responding to such emergencies, but they should never be mistaken for training procedures.

Ramona Albert (1953) once sardonically observed that roughing up an aggressive dog made about as much sense as the old rhyme: "A woman, a dog, a walnut tree; the harder you beat them the better they be." Nothing could be more futile and wrongheaded than beating an aggressive dog, but with regard to beating a walnut tree, at least such activity might be edifying for those unable to see with open eyes and heart that nothing good has ever come of hitting dogs or women. Corporal punishment is a destructive act that risks losing a dog's trust and permanently damaging the human-dog bond. Cynopraxic trainers and applied dog behaviorists would do well to exemplify in word and action the embodiment of patience and forbearance, thereby avoiding the psychological and spiritual trap of manhandling and corporal punishment as a necessity of control, which it most assuredly is not. Given the current level of practice, there is no legitimate excuse for roughing up a dog to train it. The last of a series of principles enunciated by Skinner for his utopian society Walden Two included the following item apropos to the current discussion: "Regard no practice as immutable. Change and be ready to change again. Accept no eternal verity. Experiment" (Skinner, 1979:346). Once free of the option to hit and manhandle, the training process gradually becomes more thoughtful, creative, experimental, playful, friendly and, most importantly, more successful and rewarding in terms of forming a trusting bond—an essential requirement for the control of domestic-aggression problems.

Aggression and Diet

Reduced Dietary Protein, Serotonin Production, and Aggression

Although the current evidence is equivocal with respect to the benefits of a diet containing reduced dietary protein for managing CDA, preliminary veterinary data suggest that some dogs exhibiting territorial aggression with fear may benefit from a low protein diet (Dodman et al., 1996b), especially when it is supplemented with tryptophan (De Napoli et al., 2000). De Napoli and colleagues have reported that dogs diagnosed with dominance aggression may also benefit from a low-protein diet or a high-protein diet enriched with tryptophan (see *Nutrition and Aggression* in Volume 2, Chapter 6). Salazar (2000) has proposed the hypothesis that increased insulin sensitivity to alpha-lipoic acid may influence circulating levels of tryptophan and thereby facilitate transport through the blood-brain barrier and increase its availability for serotonin synthesis (see *Diet and the Enhancement of Serotonin Production* in Volume 1, Chapter 3). Future studies using low-protein diets to modify serotonin production in dogs may want to consider the potential additive benefits of alpha-lipoic acid and dietary carbohydrates for improving tryptophan transport through the blood-brain barrier.

For various metabolic, physiological, and practical reasons, 5-hydroxytryptophan (5-HTP) may be more useful as a means for enhancing serotonin production than tryptophan. 5-HTP is the immediate precursor of serotonin and more easily crosses the blood-brain barrier than does tryptophan. Whereas the synthesis of 5-HT from tryptophan is dependent on an intermediate rate-limiting step and the availability of the enzyme tryptophan hydroxylase, 5-HTP is synthesized directly into 5-HT. Another important advantage of 5-HTP is availability. Unlike tryptophan, a product that is not currently available in a purified form over the counter, 5-HTP

can be readily purchased. 5-HTP should be handled with respect, since accidental ingestion of it by dogs can result in severe toxicosis or death. Gwaltney-Brant and colleagues (2000), who investigated several reports of 5-HTP toxicosis in dogs, found that the minimum dose producing a toxic effect in dogs was 23.6 mg/kg, with a minimum lethal dose placed at 128 mg/kg. To put these findings into perspective, a 70-pound dog would need to ingest 749 mg (15 capsules containing 50 mg each) to become sick or 4.07 g (81 capsules containing 50 mg each) to reach a lethal dose. Of course, these doses are significantly higher than the amounts used therapeutically, but the report underscores the importance of keeping all medications out of a dog's reach and giving them only under the supervision of a veterinarian.

If a low-protein diet is used, in addition to reducing protein content to 15% to 18%, dietary levels of carbohydrate and fat should be adjusted and balanced to match a dog's energy needs. Supplementing the diet with vitamin C and E, alpha-lipoic acid, and a balanced spectrum of polyunsaturated fatty acids (especially omega-3) may provide additional benefit with respect to normalizing serotonin activity and reversing neuronal damage resulting from oxidative stress. Some special and senior diets are currently available with the appropriate levels of protein, but they may need to be supplemented with additional fat and carbohydrate. Cooked salmon (1 part), turkey (1 part), spinach (2 parts), and rice (6 parts) can be prepared on a weekly basis and shaped into the form of meal-sized balls and frozen. At feeding times, the rice balls are thawed by microwave and mashed into the low-protein senior diet. High-carbohydrate snacks and drinks can also be given (e.g., a rice cake, bagel, bread, or popcorn), especially as treats or a midday snack. Care should be taken not to exceed the dog's daily caloric needs. Whenever possible, a veterinary nutritionist should be consulted to help formulate the diet and provide advice concerning supplementation. In any event, the dog's veterinarian should be consulted in advance of implementing any dietary changes or supplementation in order to obtain appropriate dosages and other relevant information (e.g., potential side effects) and potential adverse interactions with other medications that the dog might be taking. For example, 5-HTP should never be given in conjunction with selective serotonin (5-HT) reuptake inhibitors or tricyclic antidepressants.

Diet Change and the Integrate-or-Disperse Hypothesis

Hennessey and colleagues (2002) have reported that a high-quality diet (HQD) with increased levels of protein (29%) and fat (20.5%) appears to produce a calming effect when combined with a social enrichment (SE) procedure, whereas a comparison diet (CD) (23.0% protein/10.1% fat) combined with SE produces a marked increase in behavioral reactivity. Pretest and posttest scores were obtained at week 1 and again at week 8. The behavioral tests consisted of the dog being left alone in a novel environment (arena), exposure to a motionless and moving stranger, the approach of a remote-controlled toy car, and the startling blast of an air horn while alone. Dogs receiving SE were given 20 minutes of dedicated attention in a friendly room 5 days per week. SE consisted of 3 minutes of moving about freely, 7 minutes of stroking and gentle efforts to make the dog lie down on a rug, and 10 minutes of training. Dogs not receiving SE remained in their kennels. The results of this study contain paradoxical and counterintuitive trends with respect to the effects of diet and SE on anxiety and fear thresholds and raise questions with respect to potential adverse effects of dietary change and SE efforts. Further, if the study reflects actual shifts in behavioral thresholds due to dietary change and SE (not an uncontrolled influence or artifact), it raises several intriguing hypotheses with respect to the effect of diet change on the dog's responsiveness to social rewards and provides experimental support for the necessity of improving the dog's quality of life as a necessary coactive factor to achieve the bond-enhancing objectives of cynopraxis (see *Quality-of-Life Matters* in Chapter 8).

The most interesting aspect of the study is the unexpected ways in which the dogs responded to SE under the influence of the

different test diets. For example, when exposed to the previously described battery of behavioral tests, dogs fed the CD and given SE (CD/+) showed more escape attempts, panting, nervous social licking, and yawning than did counterparts fed the control diet but not given SE (CD/–). In contrast, dogs fed the HQD and given SE (HQD/+) showed significantly fewer escape attempts than did dogs fed the experimental diet but not given SE (HQD/–). Whereas the HQD/+ group panted less, produced fewer yawns, and gave fewer anxious social licks, the HQD/– group showed evidence of increased anxious arousal, producing more panting, yawning, and nervous social licking. Although the HQD/+ group showed a trend toward decreased reactivity and enhanced relaxation, the HQD/– group tended to become more anxious, but remained unchanged with respect to active reactivity measures (escape attempts). On the other hand, the CD groups showed an opposite trend of divergence with respect to the effect of SE. The CD/+ group exhibited a tendency to become more reactive and anxious, whereas the CD/– group appeared to show significantly less evidence of anxiety and reactivity. Oddly, the overall scores received by the CD/– group were comparable to the scores received by the HQD/+ group. The HQD/+ group scores were only marginally better than the CD/– group in the case of escape attempts.

These results seem to indicate that dogs fed a HQD need more social attention and care than dogs fed nutritionally adequate diets. In fact, one might surmise, that dogs fed an average diet while sheltered may be more likely to exhibit adverse behavioral and emotional changes when given more attention and care, whereas dogs fed a HQD may show increased signs of social anxiety when given less attention and care. In other words, the just-adequate diet appears to promote changes that alter a dog's response to friendly social interaction, making it subsequently more reactive and anxious to social and environmental stimuli. In contrast, the HQD appears to promote increased social anxiety in dogs that receive too little friendly interaction, but yields a calming effect in the case of dogs receiving increased friendly social contact (e.g., stroking, massage, and training). As a result, one might speculate that the HQD/+ group would tend to form more rapid social attachments than the HQD/– group, whereas the latter might show a comparatively heightened reactivity to being left alone. On the other hand, the CD/– group might show a significantly decreased ability to form new social attachments, whereas the CD/+ group might be more prone to show increasing levels of social reactivity and anxiety with respect to social stimuli and situations involving close social contact. One might further speculate that decreasing the quality of the diet more in the case of the CD groups, while at the same time rapidly increasing the complexity and quantity of social interaction given to the CD/+ group, might substantially increase anxiety and frustration, perhaps producing additional social reactivity (e.g., anxious submissiveness and threats or resentment) and an increasing trend toward self-imposed isolation. How dogs react to such hypothetical changes in diet and social interaction would probably depend on individual differences, epigenetic adversity, and allostatic load. Relevantly, Kaplan and colleagues (1996) found that cynomolgus macaques exhibit significant changes in social affiliation and agonistic behavior when fed a low-fat/low-cholesterol diet. Monkeys fed the low-fat diet while living in an unstable social setting showed more overt aggression, but when living in a stable social setting with familiar conspecifics they showed both more aggression and submission behavior and spent much less time making close tactile contact with other monkeys. Kaplan and colleagues have argued that these results are consistent with the existence of a negative-feedback mechanism between dietary privation and the expression of appropriate behavioral adjustments.

Unfortunately, the study performed by Hennessey and colleagues lacks a control group for comparing the effects of the two diets and SE against a third diet (shelter diet) common to both experimental groups prior to the beginning of the study, making a com-

parison of contrast effects on behavior between the shelter diet, the CD, and HQD a matter of speculation. However, assuming that the CD was nutritionally inferior to the shelter diet and that the HQD was superior, then the changes in the dogs' behavior may be due in large measure to the contrast detected between the new diet and the accustomed one; that is, the new diets are either better or worse than the dogs are accustomed to eat. At some level, the brain may detect and respond to such discrepancies and mobilize one of two general phylogenetic survival modes (PSMs). According to the integrate-or-disperse hypothesis, if nutritional change is experienced physiologically as better than accustomed, dogs may mobilize a *social integration strategy* and exhibit a shift of priorities toward activities and exchanges leading to improved social relations and friendly proximity-seeking behavior. On the other hand, dogs experiencing the diet change as something worse than accustomed may fall under the influence of a *loner dispersal strategy*, causing friendly interaction to paradoxically lower anxiety and reactivity thresholds.

The integrate-or-disperse hypothesis postulates that dogs receiving better-than-accustomed diets tend to respond positively to close contact and cooperative interaction because such activities are consonant with the overarching integrative PSM to form friendly social relations, but such dogs may become increasingly anxious and reactive as the result of actions leading to social isolation or rejection. Conversely, the hypothesis predicts that dogs receiving worse-than-accustomed diets, resulting in the mobilization of a dispersing PSM, will tend to become increasingly anxious and reactive subsequent to actions leading to friendly social interaction, because such activity is dissonant with the dispersal PSM. Such dogs may become more relaxed and comfortable as they are ignored and left alone, that is, when engaged in activities that are consonant with the dispersal survival modes. Accordingly, actions that are dissonant with the operative integrating or dispersing PSM result in escalating anxiety, whereas actions that are consonant with the PSM result in increasing calm and relaxation. This hypothesis points to the existence of a novel form of adaptive learning, which, if confirmed, may have powerful implications for understanding the development of emotional and behavioral disorders.

Under conditions of plenty, the most serious threat that the social animal faces is the loss of a place within the social group, that is, to be shunned or ostracized. As a result, during times of plenty, a persistent failure to experience increased social and friendly contact with others may stimulate significant uneasiness, feelings of vulnerability, and despair—a desperate plea for social attention (separation distress). Consequently, dogs operating under the influence of an integrative PSM may evidence increased social tolerance, enhanced mood, readiness to integrate new friendly relations, and calmness, developing in close association with social rewards and affectionate contact between the dog and family members. However, under the influence of diminished nutrition, physiological loss, and other quality-of-life deficiencies, priorities may turn inexorably toward self-interest and dispersion as a strategy of homeostasis and survival. In addition to a reduced ability to integrate friendly relations, the loner dispersal strategy may include increased object guarding, increased territoriality toward visitors, and intolerance toward intrusion around eating and resting places. The loner dog may tend toward activities that lead in the direction of increasing solitude (e.g., social avoidance, intolerance, and irritability). Instead of experiencing tactile stimulation and friendly interaction as being emotionally gratifying, the dog may instead become increasingly anxious and agitated by such treatment, insofar as the interaction conflicts with the mobilized dispersal survival mode. Instead of producing a physiologically calming effect, such dogs may react to petting as a stressor (see *Oxytocin-opioidergic Hypothesis* in Chapter 6). Like the reactive agonism of Kaplan's macaques fed a low-fat diet, dogs showing a loner dispersal strategy may also show increasing anxious submissiveness, aggressiveness, and intolerance (reactive agonism) in response to affectionate tactile stimulation given by family members. Whereas the social integra-

tion strategy mediates social engagement (e.g., frontal orientation, sustained eye contact, whining and howling, tolerance, increased proximity, and enjoyment of social tactile stimulation), the loner dispersal strategy mediates social disengagement (e.g., sideways orientation, refusal to make eye contact, growling, increased social distance, and increasing contact aversion). The dispersing loner may show an increasing intolerance or irritability toward family members. Under the influence of the loner dispersal strategy, the dog may become more and more prone to reactive conflict and withdrawal from social contact. If pressured for close contact or interaction, the dog may become increasingly anxious, irritable, depressed, and more aggressive—an angry loner. The angry-and-depressed coping style may be an extreme example of the loner dispersal strategy, perhaps helping to make sense of the reactive aggression shown by some dogs in response to the most benign and friendly handling by family members. For such dogs, operating under an actual or perceived state of privation, affectionate contact may be paradoxically anxiogenic and irritating. As circumstances become worse, the reaction to social comfort and contact may become more and more debilitating. In contrast, as the dog's circumstances or quality of life improves, its response to social contact and its willingness to integrate friendly relations should correspondingly make progress.

Interestingly, the integrate-or-disperse hypothesis may help to explain the temporary aggression-reducing value of the social-deprivation procedure previously discussed (see *Nothing in Life Is Free, Subordinate Postures, and Rank*). By withholding social contact from a dog operating under a loner-dispersal strategy, its anxiety and reactivity may be significantly reduced as it engages in activity consonant with the dispersal ESS. From this perspective, the procedure has little to do with the idea of changing a dog's perception of rank, but may mediate a calming effect by simply leaving the dog alone and preventing it from engaging in social activity dissonant with the dispersal ESS. However, if true, the procedure works with a severe cost with respect to a dog's capacity to ultimately integrate friendly relations with the family, since it only serves to polarize the dog further. In contrast, instead of promoting social avoidance and withdrawal, the integrate-or-disperse hypothesis predicts that improving a dog's quality of life through diet, exercise, play, and minimized confinement may be sufficient to mobilize a social integration strategy, thereby reversing the dog's adverse response to social rewards and enabling it to integrate friendly social relations with family members without experiencing paradoxical anxiety.

The cynopraxic therapy process works only to the extent that both social and quality of life imperatives are satisfied, that is, the procedure used must both enhance the bond while improving the dog's quality of life. Provided that the integrate-or-disperse hypothesis is generally accurate, then gradually enhancing the quality of the dog's diet and the quality of other prominent aspects of its life would seem to be a logical and useful starting point in the treatment of CDA and other problems involving a failure of the dog to integrate friendly household relations. Even if the foregoing hypothesis concerning the precise causes turns out to be wrong, the value of improving the dog's diet and quality of life will remain a valid and useful way to initiate cynopraxic therapy.

Fat, Cholesterol, Fatty Acids, and Impulsive Aggression

In the experiment performed by Hennessey and colleagues, a significant aspect of the diet change was an alteration of fat content. The HQD contained twice as much fat as the CD together with a significant increase in protein. They found no evidence in support of the notion that a high-protein diet might promote aggressiveness or irritability. One possible alternative explanation for the benefits observed in dogs fed a reduced protein diet is the fat content of the diet. Dodman and colleagues (1996b) adjusted the energy density of their different diets by manipulating fat content. The fat content of the high (h), medium (m), and low (l) protein diets were adjusted in stepwise fashion from 27.5 (h) to

36.8 (m) to 44.8 (g/1000 kcal), respectively. Large adjustments in dietary fat content were carried out in the study performed by De Napoli and colleagues (2000). In this experiment, the low-protein diet contained five times as much fat as the high-protein diet. Although neither study controlled fat content as a potential therapeutic variable, dietary fat and cholesterol levels may exert a significant influence on serotonergic function and confound the modest behavioral effects attributed to increased tryptophan. The notion that a change in fat and cholesterol intake might influence reactivity and impulsive aggression has been a topic of considerable experimental interest, and numerous studies have shown evidence of a link between low cholesterol, reduced 5-HT activity, and various adverse impulse and mood (depression) effects, including an increased propensity for impulsive aggression (Buydens-Branchey et al., 2000; Golomb et al., 2000). As previously discussed, monkeys fed a low-fat and low-cholesterol diet are more aggressive and less friendly than monkeys fed a high-fat and high-cholesterol diet; such monkeys also have lower cerebrospinal fluid concentrations of the serotonin metabolite 5-hydroxyindoleacetic acid (5-HIAA) (Kaplan et al., 1994), suggesting a potential mechanism for the change in social agonism. Accumulating evidence appears to support the notion that low cholesterol is not merely of correlational interest, but may play a causative role in the process of producing serotonergic abnormalities (Brunner et al., 2002). The effect of fat and cholesterol on behavior and mood appears to be dose dependent, since excessively high cholesterol levels also appear to produce adverse effects on impulse control (Hilakivi-Clarke et al., 1996), suggesting that some optimal level is necessary for efficient serotonergic functioning and for producing preventive or therapeutic benefits (Hillbrand and Spitz, 1999).

Other lines of evidence suggest that low cholesterol may not be as critical a measure or predictor of impulsive aggression as low levels of omega-3 polyunsaturated fatty acids (PUFAs) (Hibbeln et al., 1998; Rogers, 2001). Omega-3 deficiencies have been identified in children exhibiting behavioral and cognitive deficits associated with attention-deficit hyperactivity disorder (e.g., learning difficulties, inattentiveness, and impulsivity) (Stevens et al., 1996), symptoms that are ameliorated by PUFA supplementation (Richardson and Puri, 2002). Omega-3 supplementation has also been shown to stabilize mood, reducing the severity of human depression and mania (Freeman, 2000). Finally, the oxidative depletion of essential fatty acids within the neuronal cell membrane has been implicated as a major factor in the progress of psychotic disorder, with supplemental PUFAs and antioxidants providing therapeutic benefits by helping to repair damage done to the cell membrane by oxidative stress (Mahadik et al., 2001). Interesting preliminary evidence suggests that supplementing the diet with PUFAs, especially omega-3 [eicosapentanoic acid (EPA) and docosahexanoic acid (DHA)] may enhance central serotonin function and reduce impulsive behavior, including aggression (Brunner et al., 2002). The clinical value of these dietary manipulations for dogs exhibiting CDA and other behavior problems has not been evaluated, but one double-blind, controlled trial has demonstrated mood-stabilizing efficacy in human bipolar patients (Stoll et al., 1999). A relatively high dose was used (omega-3 fatty acid: 6.2 g EPA and 3.4 g DHA divided in two daily doses). A recently reported trial involving briefer treatment and a lower dose of DHA alone (without EPA) proved ineffective for major depression. The foregoing data suggest strongly that cholesterol and/or PUFA plasma levels may represent a useful diagnostic marker and etiological factor in the development of CDA. Veterinary clinical investigation of cholesterol and PUFA levels in aggressive and nonaggressive dogs would seem justified.

Protective and Restorative Effects of Vitamins and Antioxidants

Dogs under chronic stress and increased metabolic strain may benefit from preventive measures taken to reduce neuronal damage due to oxidative stress. The brain may be particularly vulnerable to such damage as the

result of increased metabolic activity associated with chronic stress and the maintenance of a reactive coping style. Diets enriched with antioxidants such as vitamins C and E and alpha-lipoic acid may exert significant neuroprotective effects (Packer et al., 1997) or reverse adverse cognitive changes associated with aging in dogs (Milgram et al., 2002) (see *Diet and Exercise* in Chapter 3). In addition to potent antioxidant effects, alpha-lipoic acid has been found to increase dopamine, norepinephrine, and serotonin activity in aging rats (Arivazhagan and Panneerselvam, 2002), perhaps helping to explain some of the cognitive benefits observed in older dogs fed diets containing increased levels of the substance (Milgram et al., 2002). Vitamin C and vitamin E perform complementary water-soluble and fat-soluble antioxidant functions. Normally, a dog's need for vitamin C is at least minimally satisfied by endogenous synthesis; however, as the result elevated allostatic load, the requirement for vitamin C may increase. Also, dietary supplementation of vitamin E and PUFAs may produce an increased demand for vitamin C. Vitamin C may influence vitamin-E potency and help prevent the propagation free radicals (Mahadik et al., 2001; Milgram et al., 2002). Interestingly, vitamin C is rapidly absorbed after ingestion, suggesting that dogs may have an active intestinal transport mechanism to increase the absorption of vitamin C (Wang et al., 2001). Dogs have evolved the ability to taste furaneol, a sweet flavor associated with fruits (see *Gustation* in Volume 1, Chapter 4). The ability to efficiently absorb vitamin C combined with the presence of gustatory receptors dedicated to the taste of fruity flavors suggests that vitamin C may possess an underappreciated physiological significance for dogs.

EXERCISE

Some data suggest that exercise may exert a significant modulatory effect over biological stress as well as influence the activity of various neurotransmitter systems (see *Exercise and the Neuroeconomy of Stress* in Volume 1, Chapter 3). These general physiological effects of exercise may help to account for the lower incidence of dominance- and possession-related aggression occurring in dogs obtained for the purpose of exercise (Jagoe and Serpell, 1996). Putting a dog outside in a fenced yard or on a run line is not enough to ensure adequate exercise (Delude, 1991). To produce a benefit, the owner must become directly involved in the exercise activity, ensuring that the exercise (walking, running, jumping, fetching, and so forth) is done in way that produces physiological and psychological benefit.

BRIEF PROTOCOLS FOR CANINE DOMESTIC AGGRESSION

Assessing and modifying aggression in adult dogs is complicated by a dearth of reliable scientific and technical information with which to construct rational treatment protocols. Most of the current literature is composed of clinical impressions, case histories, anecdotes, and statistical analyses of questionnaires. Such methodology is subject to many confounding influences, not the least of which are the investigator's personal biases and beliefs. Although such information may offer promising insights from time to time, it is also prone to an opposite effect: the perpetuation of unfounded opinions and "cherished preconceptions." Few of the contemporary treatment protocols used to control or manage CDA have been subjected to rigorous clinical evaluation and validation. Clearly, much more needs to be done by way of basic and clinical research to advance our knowledge about how to best treat dog aggression problems. In any case, there are no cookbook procedures for controlling aggression, and effective intervention depends on both theoretical and applied knowledge together with competent skills and practical experience acquired as the result of treating such problems.

Assessment and Treatment Priorities

All provocative situations and control incentives that have been associated with aggressive threats or attacks in the past should be identified and evaluated (see *Assessment and Identification* in Volume 2, Chapter 8) (Table 7.4). Many domestic aggressors threaten or

bite in more than one situation. In addition to identifying the situations where aggression occurs, potential motivational factors should be explored, including emotional establishing operations (e.g., fear, anxiety, frustration, irritability, or anger). In many cases, these various emotional influences are coactive and present in varying proportions and admixtures. Frequently, domestic aggressors show evidence of fear just before or after biting, leading to a widely held belief that all such attacks are motivated by fear. Although fear appears to play an active motivational role in triggering or escalating some forms of CDA, it also exerts a strong inhibitory effect over many forms of aggression. Fear occurring just before an attack in association with threat displays may serve to stop or reduce the severity of the resulting bite, whereas fear occurring during an attack may either serve to limit the attack or cause it to rapidly escalate, as is prone to occur in response to inappropriate punishment. An aggressive dog's reliance on threat displays belies a significant amount of fear and conflict; otherwise, the dog would not hesitate and threaten before launching into an attack. The fearlessness associated with some forms of panic-related aggression may be responsible for the lack of threat and warning before a dog launches into a hard, uninhibited attack. In such cases, efforts to instill fear may worsen the aggressive response. The presence of fear in association with threats may help to explain the greater sensitivity and responsiveness of the threat sequence to the inhibitory effects of punishment. Although punishment may be more likely to interrupt and prevent an aggressive episode at the threat sequence, it does so at the risk of suppressing the threat display without reducing the dog's propensity to attack. In cases involving dogs that are aggressively reactive to fear-eliciting stimulation, such treatment also runs the risk of triggering an overt attack that might not have occurred without the punitive stimulation.

The role of fear in aggression is complicated. Fear reduction should be primarily the result of increased feelings of safety and trust occurring in association with enhanced interaction between the dog and the owner. Placing too much emphasis on fear reduction by means of situational counterconditioning efforts or medication may not significantly improve the overall situation and long-term prognosis, but may inadvertently make things worse, perhaps even more dangerous (see *Pharmacological Control of Anxiety and Fear* in Chapter 3). For example, tranquilization appears to cause wolves to become more aggressive and more likely to attack without giving threat displays (Woolpy and Ginsburg, 1967). In addition to evaluating control incentives, trainers should carefully assess and address coactive emotional factors, such as anger, frustration, irritability, and panic (loss of control). The role of fear in aggression varies significantly under influence of different control incentives and coactive emotional influences. Dogs showing fear while exhibiting aggression in the context of object guarding represent a significantly different diagnostic picture than dogs showing fear and aggression while their paws are handled. Although graduated counterconditioning is effective and can be used to reduce specific fears, behavior therapy of aggression problems occurring in associated with control-related incentives should stress training activities that teach the dog and owner how to cope more competently and confidently with provocative situations. Without such a broad-based cynopraxic approach to such problems, the dog may learn not to bite in the specific situation treated with counterconditioning, but still harbor a control-related propensity to threaten or bite the owner in other provocative situations involving other control incentives.

Many situations leading to CDA are associated with a loss of safety or comfort. Under circumstances resulting in the loss of safety or comfort, predisposed dogs may threaten or attack under varying coactive emotional influences, including irritability, anger, frustration, and fear. Both control-related aggression and panic-related aggression occur under the influence of such provocative stimulation. Dogs exhibiting control-related aggression most often present threats and inhibited punitive attacks. In contrast, dogs exhibiting

TABLE 7.4. Common situations and triggers provoking aggression in dogs

When the dog is approached while in close proximity or in possession of toys, food or food bowls, and other prized objects (possessive aggression)
When the dog is approached while occupying a resting place
When a person enters a certain room while occupied by the dog
When a person is putting a collar on the dog or grabbing the collar
When the dog's leash is yanked
When the dog threatens some person or dog but turns the attack toward someone else who is closer or attempts to restrain it (redirected aggression)
When the dog is shouted at loudly
When the dog is being forced into its crate
When the dog is physically displaced from the bed or favorite pieces of furniture
When the dog is approached while resting or sleeping in or near doorways
When the owner is leaving the home
When the dog is approached directly, reached for, or stepped over
When the dog is near a particular family member
When the dog is being picked up, manually restrained, or physically threatened
When the dog is touched in a particular place (e.g., top of head, shoulder, belly, feet, or hindquarters)
When the dog is given unwelcome affection or petting
When the dog is being groomed (brushing, trimming nails, cleaning ears, or bathing)

panic-related aggression show a significant degree of dyscontrol over aggressive impulses, representing a significantly more dangerous problem. Panic aggressors often appear to attack incompetently and impulsively, reacting in the most violent and uninhibited ways to the most innocuous and trifling intrusions or interferences disturbing their comfort or safety. Such dogs seem to lack a normal degree of social flexibility and tolerance. Panic-related attacks frequently occur under the prompting of heightened autonomic reactivity, anger, fear, rigidity, and the momentarily loss of impulse control. In contrast to control-related and avoidance-related aggression, panic-related aggression appears to occur as the result of an incompetent loss of impulse control. Physical punishment in such cases serves only to further heighten aggressive arousal, perhaps because of a fear-mediated excitatory influence on anger/rage circuits.

Domestic aggressors often show affection toward their victims, but appear to tolerate innocuous intrusion, interference, or loss. Without the formation of an affectionate bond based on trust, the daily interaction between the owner and the dog may be vulnerable to the adverse effects of interactive conflict and stress. The resulting stress-related autonomic and behavioral changes may contribute to the development of CDA. Some domestic aggressors show a persistent intolerance to the affectionate and playful overtures of certain family members while tolerantly accepting the affection from others. In addition to showing intolerance and increased irritability, these dogs may show varying levels of resentment toward physical handling and control, increased emotional reactivity and vigilance, rigidity, and a lack of responsiveness to play. Such dogs appear to actively resist the rejected family member's efforts to establish a close connection and may deliver a hard bite while being hugged or petted affectionately. In the absence of affectionate trust or willingness to form an affectionate relationship, pet-

ting, handling, and invitations to play might naturally become sources of resentment and irritation and, in some cases, set the occasion for aggressive reprisals (see *Loss of Safety, Depression, Panic, and Aggression*).

Aggression Associated with Disturbances While Resting

Dogs exhibiting aggressive tensions, threats, or overt biting when approached while in certain locations, such as doorways, near feeding areas, or beds, should be trained to leave such areas by vocal and hand signal, rather than reaching for them or attempting to displace them manually. Cooperative compliance at such times is appropriately rewarded with affectionate vocal encouragement and food rewards or by providing the dog with activities that it enjoys (e.g., going for a walk or play). Eventually, the dog acquires a something-positive-is-about-to-happen-to-me expectation whenever the owner approaches. Training a dog to orient in response to its name and to hold its attention briefly on the owner is an important aspect of this training process. The orienting and attending response is repeated frequently from different directions and while approaching the dog in different ways. The dog gradually learns to orient and make sustained eye contact with the owner before being rewarded. Various types of approaches including slow, normal, and fast movements toward the dog are associated with the sequence of calling its name, holding its attention, and tossing it a treat. In some cases, a squeaker containing an odor previously paired with PFR training is used as an orienting stimulus—a procedure that is especially useful while working with a dog at close quarters or when prompting it from a hypnagogic or sleeping state. The odor provides contextual and associative information stemming from PFR training that may compete with or restrain aggressive arousal. Alternatively, during approach and attention therapy, the odor can be put on hands and clothing or sprayed into the air by a plant mister or a modified carbon-dioxide (CO_2) pump. At times when the dog must be awakened, its name is called or the squeaker is used. Orienting and attending training helps to condition a positive anticipatory response in association with being awakened or disturbed. The orderly presentation of training events associated with attention therapy serves to enhance executive control over impulse. Attention therapy also improves the likelihood that a dog is orienting and attending to training events and getting the most from counterconditioning and other behavioral procedures.

Dogs that threaten or bite if they are disturbed or moved while resting or sleeping should also be trained to defer to command in situations where they have exhibited aggression in the past. Frequently, these locations involve furniture or a bed, but it can be any place where the dog habitually rests, including the owner's lap. In addition to preliminaries already discussed, such dogs should be trained to surrender defended areas on the command ("Off") and do so without hesitation or resistance. Such training is performed with the dog kept on leash and collar or halter to make handling and control more safe and effective. The dog is trained to both jump onto ("Hup") and off furniture in various locations around the house. The on-off ritual is repeated until the dog's performance is fluid and brought under the control of both voice command and hand signal. Initially, the dog is prompted to leave furniture by gesture or by tossing a treat some distance away, requiring that it get up to retrieve the food. Tossing a ball or some other valued toy can also be used to prompt the off action. The hand movement used to toss the treat is incorporated as a hand signal by gradually fading the treat. As the dog takes its reward for getting off, it is called back and prompted by gesture to jump back up on the furniture and rewarded again. Other resting places associated with previous threats or attacks should be identified and treated in a similar way. If the dog shows overt aggressive actions, it is appropriately directed off the furniture by leash and hauled off to TO. Once a dog is trained to jump on and off furniture, the owner should allow the dog to get up on furniture only after it sits and waits for an invitation to jump up. Dogs that have seriously threatened or have bitten while on a bed

should be restricted from such access and learn to sleep on the floor or in a crate, if necessary.

Aggression Associated with Social Signals and Intrusive Movements

In addition to training the dog to perform various cooperative behaviors incompatible with aggression, the predictive and emotional significance of social signals are modified by linking them with prosocial exchanges incompatible with aggression. Social signals provide the dog with predictive information about what is most likely to occur in the immediate future, thereby motivationally preparing it to cope effectively with the impending social situation (see *Social Communication and the Regulation of Aggression*). For example, some dogs by virtue of severe or repeated noncontingent punishment in the past, may become aggressively aroused when exposed to social and contextual stimuli that resemble those present at the time of event. A wide variety of social signals occurring immediately before the event may acquire provocative significance via classical conditioning, including loud voices, staring, the smell of anger, standing over, raised hand, quick movement, reaching actions, grabbing, or touching, and patting. Many of these social signals (e.g., loud voices, fast movements, and smells of anger) may be biologically prepared for rapid conditioning and the formation of associative linkages with anger and fear. As a result of such conditioning, subtle and benign movements may provoke aggressive arousal, especially when they occur under the influence of contextual cues similar to those present at the time of the original provocative event. In addition to external contextual stimuli, internal contextual stimuli consisting of mood and emotional changes also contribute to setting occasions in which aggression is most likely to occur. Together with external and internal contextual cues, the dog's activity and body posture at the time of the event may have been strongly associated with the traumatic event. After identifying these various provoking social and contextual stimuli, they are hierarchically organized in accordance with their provocative potential. The preparatory aversive arousal associated with these various stimuli and contextual settings is gradually modified by a pattern of rewarding and safe exchanges that promotes social expectancies and emotional establishing operations incompatible with reactive arousal and aggression.

Aggression Associated with Guarding and Possessiveness

Possessive guarding of food and toys is a common dog aggression problem. From the results of a large survey (N = 3226), Guy and colleagues (2001a) found that approximately 20% of dogs either growled or snapped while in possession of toys, food, or other objects. Dogs are often highly selective about the sort of items that they defend, and removing those items from the house can be a helpful preventive measure. Object guarding and possessiveness are not necessarily indicators of dominance, even though superficially the behavior appears to be motivated by dominance-related incentives. Among wolves, there is little correspondence between object guarding and dominance, with wolves of all ranks exhibiting heightened possessiveness over objects located within their ownership zone around the mouth. In addition, all wolves, regardless of rank, will attempt to steal food from other wolves irrespective of dominance (Mech, 1999). Competition between the owner and the dog over the control of forbidden objects appears to magnify the perceived value of the objects and to promote guarding incentives. A history of chasing, cornering, capturing, restraining, punishing, and the forceful extraction of objects from the dog's mouth may stimulate a problematic control incentive associated with possessions, especially involving objects possessing significant appetitive value for the dog. The appetitive motivations associated with guarding behavior suggest that the behavior is not under a strong influence of fear, but is primarily associated with comfort-loss incentive under the coactive influences of anxiety, frustration, and anger. Dogs affected by low anger/rage thresholds and high excitability levels are particularly prone to serious aggres-

sion problems occurring in association with object guarding.

Dogs that grab, run off, and guard objects frequently exhibit aggression problems involving hard bites to family members, and these problems require significant retraining and owner education to resolve. Such dogs should not be chased or challenged when they possess objects. The best method for the treatment of such problems is prevention. A high correlation seems to exist between the activity of grabbing forbidden objects and provoking a chase-and-evade game with the owner and the later development of object-related aggression. Puppies and dogs that engage in this sort of behavior should be encouraged to bring such items back to the owner in exchange for a treats and other rewards. Dogs that refuse to exchange an object for a treat can often be enticed to come by ringing a doorbell, shaking a set of car keys, or picking up a leash. Once the object is retrieved, the dog is put on a leash as necessary for added control and safety, and the forbidden object is placed on the floor with the voice signal "Leave it." If the dog approaches the object, the trainer says "Leave it" in a firm voice and, if necessary, prompts the dog with the leash to leave the object. If the dog turns away from the object, it is rewarded with praise, food, and an alternative item that is both acceptable for chewing purposes and attractive for fetching. This general procedure is repeated until the dog avoids the object in a variety of situations. The subsequent steps in this process are described in Chapter 2 (see *Controlling Inappropriate Chewing Activities*).

Dogs that show a guarding response while eating represent a significant threat to family members, especially young children who may not be appropriately respectful of the dog's need for space while eating. Again, prevention is the key to avoiding such problems. The common practice of repeatedly taking a puppy's food bowl away while it is eating does not appear to be useful and may actually make matters worse. The best strategy is to train the puppy to expect that it will get something, rather than lose something, when it is approached while eating. Feeding each meal in several small portions appears to help reduce negative tensions around the food bowl. Feeding with two bowls can also be used in a similar way, allowing the owner to place food unobtrusively into one of the bowls while the dog is eating from the other one. Changing the type of food fed, the type of bowls used, and the schedule and location of feeding may help to reduce stimulus and contextual cues associated with possessive reactivity. In some cases, decreasing the appetitive value and palatability of the food may help to reduce the dog's incentive to guard it. The trainer can restrain the dog on leash or tie-out and use a probe stick or broom handle to move the food bowl away from the dog, thereby getting some indication of the dog's level of reactivity. The absence of an aggressive response to such intrusion is not necessarily a reliable indicator of safety from a potential attack, however. Dogs showing food-guarding reactivity should receive intensive basic training and exposure to various object-guarding techniques and restraint measures as needed to reduce reactivity occurring in association with intrusions while eating. At a minimum, such dogs should be kept on leash and trained to wait in a sit-stay before being released on cue to eat. They should also learn to leave the bowl on voice command and wait at a distance as an attractive food item is put into the bowl, whereupon they are released to take it. When approaching a dog while it is eating, the practice of tossing food items of varying value near or into the food bowl can also be helpful. Food guarding should be treated with a high-degree concern and with many of the same precautions and techniques described for object-guarding behavior. Although many of these dogs limit their agitation to becoming uncomfortable, stiff, and vigilant around the bowl, some excitable and highly food-motivated dogs have delivered severe and unexpected attacks following a history of low-grade threats and snaps. Dogs that are given training before they reach the stage of hard biting appear to be significantly less likely to escalate their aggressive efforts around food. Food guarding can be managed by simply avoiding contact and not interfering with the dog while it is eating, except as required for countercondi-

tioning efforts. Dogs that show a high level of agitation while eating should be fed in a separate room from people or other dogs or crated as a further precaution and safety measure.

Object guarding is a common source of dangerous control-related aggression. Attacks associated with possessive aggression present with a great range of potential danger and variety, requiring careful assessment and evaluation that take into account the risk of future attacks against family members. Object guarding and possessive aggression are particularly problematic in busy households with children and visitors who may inadvertently come into contact with the possessive aggressor while it is in possession of a protected object. Severe object-guarding threats and biting sometimes occur without much warning in response to minor intrusive threats. Other dogs attack with inhibited snaps or bites only after a significant amount of intrusive interference has transpired around the protected object in the presence of various threats and warnings by the dog. Dogs exhibiting the first pattern of object guarding in association with hard biting present a guarded prognosis and should be removed from homes with children. The second group of dogs are generally more responsive to training efforts, but may still represent a significant threat to children or others coming into contact with them under adverse circumstances. Although such dogs may pose a risk, it is often one that can be managed with common sense, conscientious precautions, and a lifelong commitment to the dog's training. Hard decisions sometimes need to be made regarding object-guarding dogs, and those decisions should error on the side of safety, especially in the case of children. Object-guarding aggression has resulted in severe and disfiguring facial bites suffered by children while they were innocuously reaching toward, leaning over, snuggling, or playing tug with an object-guarding dog. A dog that has delivered an uninhibited hard bite in the context of food or object guarding should be considered prima facie at risk of biting under similar circumstances in the future; no matter what treatment is used to control the behavior and no matter how successful it appears to be, the risk may continue permanently despite the appearance of improvement.

Object guarding can be divided into five stages of escalating threat and propensity for attack: conflict, challenge, critical point, crisis, and panic. These stages are exhibited in varying degrees by food- and object-guarding dogs. Approaching an object-possessive dog while it is occupied with a prized object often causes the dog to slightly or greatly stiffen with anticipation of interference—the first overt sign of aggressive tension. The stiffening response reflects conflict-related autonomic change elicited by an expectancy of impending loss. Conflict associated with anticipated loss is followed by the dog picking up the object and evading the owner or remaining near the object, possibly under the influence of a mounting control incentive as the owner gets closer. As the owner approaches beyond the conflict point, dogs prone to guard and defend objects show an increasing anticipatory vigilance and readiness to resist or challenge the owner. If the owner advances closer and reaches toward the dog, the challenge is brought to a critical point with the dog making a rapid choice to allow the owner to intrude safely or to intensify the rising threat, sometimes leading to a sidelong preemptive snap or loss of nerve and retreat with the object. If the dog intensifies the threat, what occurs next depends on how the owner responds. If the owner backs off, the dog's guarding response may be reinforced, thereby strengthening guarding and other behaviors operating under similar control-related incentives in the future. If the owner persists and intrudes further or attempts to take the object, the dog may deliver a protective snap or bite. In the case of highly reactive and incompetent dogs, a panic point may be rapidly reached that causes the dog to dramatically intensify its threat or compels the release of a hard and uninhibited bite. From the critical point forward, the situation becomes progressively problematic, finally becoming a no-win situation. Punishment at any of these points may result in a rapid escalation and worsening of the problem. Following punishment, the protective response may occur at an earlier point in the sequence (e.g., conflict or

challenge) or else cause the dog to inhibit threats until a crisis or panic level of arousal is reached, thereby possibly making the attack more dangerous and difficult to anticipate. Instead of excessive reliance on confrontational procedures, various behavior-therapy techniques can be used to reduce guarding behavior by means of counterconditioning, response prevention, and training the dog to relinquish objects under a positive expectancy of gain by way of reward rather than loss.

Dogs that persistently guard objects may require intensive preliminary basic training and behavior therapy to establish a reliable willingness to relinquish guarded objects. At minimum, the dog should receive several sessions of attention conditioning, sit-stay and down-stay and back and wait training, and be trained to take, fetch, and release toys that have not been protected in the past. A major focus of therapy is to facilitate a bond of trust that is incompatible with autoprotective incentives. The object-guarding dog is kept on leash and limited-slip collar or muzzle-clamping halter during all training procedures. Dogs exhibiting a serious potential risk for aggression should be restrained on a tie-out or active-control line during graduated challenges. An active-control line is made by hooking a carabiner to a loop of nylon that has been fastened to some immovable object (see *Walking Stand-Stay and Distance Exercises* in Chapter 1). Alternatively, a heavy eyehook can be screwed into sturdy molding. Depending on need, a 6-foot leash or a 15-foot long line is passed through the eyehook and attached to the dog's collar or halter, thus securing active control over the dog while performing object-guarding procedures. By pulling back on the line, the dog is turned away from the object and forced toward the anchored eyehook. An additional safety consideration is to attach a length of light rope to objects before presenting them to the dog (object line), thereby preserving a means to take objects away from the dog with less risk of getting bitten in the process.

Training is initiated with attention therapy and reward-based ICT. With a foundation of enhanced attention and impulse control, the object-guarding dog is first trained to take and then release various objects in exchange for a treat. Objects are introduced in accordance with their potential for provoking a guarding response. Training the dog to release objects should begin with objects that the dog is least likely to guard and then gradually moving to items that it is more likely to guard. Slowly progressing through these items without evoking threats makes the process safer and more likely to succeed. The first step is to train the dog to take ("Take it") and release a neutral item (e.g., a toy) to the hand ("Out") or to the floor ("Drop it"). With the object in the dog's mouth, the trainer says "Out" as a closed hand with a treat in it is presented to the dog. As the result of preliminary basic training, most dogs will release the object in order to obtain the treat. The size and type of food reward should be varied, but all treats used during such training should be highly attractive to the dog. After eating the treat, the object is given back to the dog after it sits on command and waits for a variable length of time. In cases involving a greater threat, the dog is trained to back away from the object after dropping it and to sit or lie down before it is rewarded. With the dog in the sit-stay (a response that should be well conditioned in the context of preliminary attention training), the trainer picks up the object, rewards the dog with a treat, and then returns the object to the dog.

The backing, sit or down, and waiting responses are facilitated by attention-controlling prompts delivered by means of the control line. These various responses should be brought under appropriate vocal and hand signal control (e.g., "Back," "Stay," "Wait," and "Take it"). The next step is to prompt the dog to remain in a sit or down-stay by saying "Stay" as the valued object is tossed out of its reach. If the dog moves toward the object, the action is abruptly blocked with the control line, and a confident vocal command "Stay" is delivered. During the brief waiting period, the dog is prompted to turn its attention toward the trainer in response to a smooch or squeaker sound, followed by a click, flick of the right hand, and the delivery of a food reward. Finally, the trainer retrieves the object and gives it back to the dog as a

reward for its cooperation. The dog is also trained to pick up objects, drop them, and back away from them or, if the dog refuses to pick up objects, it is trained to back away from a tossed object, whereupon the trainer retrieves it and gives it to the dog. Whenever safe to do so, the dog should be trained to play a tug-and-fetch game with a variety of items, thereby helping to reduce competitive tensions while increasing cooperation and trust. After the item is dropped, the trainer signals the dog to "Back" and repeatedly tugs into the control line to prompt the backing response. If the dog refuses to drop the object after picking it up, it is pulled gently from its mouth by the object line. As the object is released, the dog is rewarded and then prompted to back away. If the dog refuses to release the object, the control line is pulled back as the object line is pulled harder, as necessary to compel the dog to release the object. The dog is always rewarded after releasing the object, often by allowing it to approach and take the object on signal or by tossing the object for the dog to fetch. This general procedure is repeated until the dog releases the item without objection or hesitation and backs away under vocal command and hand signal. Delayed prompting and fading of the control line together with various startle-type tools and strategies, as needed, are used to gradually achieve the backing and stay response. To be effective, these procedures require a high degree of diligence and daily practice and a strong foundation of basic training. Owners not likely to follow through with the dedication needed to succeed or lacking the necessary aptitude should not be encouraged to pursue it in the first place.

As the dog's response improves, progressively more natural circumstances can be introduced until it readily drops and backs away from objects on command. In cases where risk permits, daily object play involving tug-and-fetch games and variations on the release, sit-stay or down-stay, attention, wait, back, and fetch modules and routines should be practiced in the context of nonthreatening retrieve games with objects that the dog is unlikely to defend.

In some cases, once preliminary training has been successful, remote training (electrical and spray devices) can be used to establish a higher level of compliance over the dropping, backing, and the stay responses. Such training should involve a competent introduction of remote training in advance of using electrical stimulation to control possessive behavior (see *Electronic Training and Problem Solving*, Chapter 9). Remote electronic training can help to enhance impulse control while appearing to produce beneficial secondary effects conducive to the enhancement of relaxation and safety (Tortora, 1983) and to enforce compliance once behavioral control has been established via reward training (Borchelt and Voith, 1996). A significant advantage of electrical training for managing aggression problems is that it can be used to capture a dog's attention and reliably prompt behavioral adjustments at a distance and without necessitating that the trainer make risky direct contact with the dog. Radio-activated electronic devices can deliver a controlled motivational state conducive to inhibition, but without associating the event with the trainer as the source, something not possible in the case of interactive punishment. Also, the stimulus remains consistent, steady throughout, and inescapable by means of aggressive reprisals, thereby minimizing the risk of reinforcing undesirable behavior.

The dog first learns how to escape a low-level electrical stimulus and then to avoid stimulation by performing various responses in accord with vocal commands, hand signals, and prompts (see *Remote Electronic Training* in Chapter 9). Special emphasis is placed on attention training, stay, recall, and the enhancement of emergency exercises (e.g., quick-sit and instant-down). With every successful escape or avoidance response, petting and massage are given to overlap with relief and safety from the electrical stimulus. In addition to relief and safety, the discontinuation of the electrical stimulus results in a progressive state of increasing relaxation, an opportune source of stimulation conducive to social-contact tolerance. As the result of orderly electrical training, a dog gradually learns that it can predict and control the aver-

sive electrical event by responding cooperatively to the trainer's signals and prompts. These various skills promote increased social competence, confidence, and relaxation in the dog, thereby helping it to learn how to cope in a more constructive and organized way when faced with other forms of provocative social stimulation involving threats of comfort or safety loss. Electrical stimulation can also be used in the context of back, wait, and halt-stay training. With such preliminary training in place, the electrical stimulus can be introduced into the context of object guarding, as a means to compel the dog to drop, back away, and stay at a distance from guarded objects until it is released by the trainer. With the offset of stimulation, an immediate relief response is followed by a slower and progressive relaxation response. During the course of relief/relaxation, the trainer provides the dog with vocal reassurance, petting, and massage, as can be safely performed. An olfactory safety signal can be presented at such times for the purpose of capturing and generalizing the safety-relaxation effect to other situations in which such a conditioned modulatory effect might helpful. The odor is further conditioned in association with PFR training and used in the context of graduated counterconditioning efforts. Of course, appropriate restraint (e.g., limit-slip or muzzling-type halter) and other safety precautions need to be taken at all times when working with a potentially dangerous dog (secure tie-out or active-control line). Electrical training in the context of managing aggressive behavior should be performed in the spirit of opening a window of opportunity for additional reward-based training activities aimed at conditioning behavior incompatible with aggression. The foregoing is a brief overview of steps used to manage one form of control-related aggression involving refractory object guarding. As a last resort, such training may produce a significant benefit when applied in conjunction with complementary behavior-therapy techniques. The procedure requires a high degree of skill and experience with dog aggression and electronic training and should be attempted only under the supervision of a highly skilled applied dog behaviorist or cynopraxic trainer well versed in such training procedures.

PART 3: CHILDREN AND DOG AGGRESSION

Infants and Dogs: Toward the Prevention of Problems

Dogs exhibiting active aggression problems represent a significant risk to children living in the household. Whenever possible, dogs exhibiting an excitable and reactive temperament with a demonstrated propensity to bite should be removed from homes with children. These dogs often do well in homes with adult owners, and rehoming should always be explored before more drastic measures are considered (see *Evaluating the Risk* in Volume 2, Chapter 6). Although such dogs represent an unacceptable threat to children, the majority of dogs are friendly and gentle companions for children. Even so, precautions should be taken to prevent interaction between children and dogs that may lead to an increased risk of biting or injury associated with inappropriate intrusiveness or overactivity.

Trainers are often consulted for advice regarding the best ways to introduce an infant to the family dog. The key to making this critical transition a successful one is careful preparation in advance of the infant's arrival. These preparations include selection, socialization, basic training and behavior management, counterconditioning and desensitization, exposure-habituation, and establishing a daily routine consistent with the way things will be when the baby comes home.

Selection

Advanced preparation begins with the selection of the dog. Thoughtful breed and breeder selection can help to reduce the risk of problems by increasing the likelihood that the dog is successfully matched to the owner's level of dog savvy and the needs of the household. Selective breeding has resulted in significant alterations in behavioral thresholds and temperament traits. In addition to breed-specific characteristics, individual differences predispose dogs toward behavior conducive to

interaction with children or not. Obviously, highly excitable dogs bred for wariness and guarding behavior, or those exhibiting reactive fear, aggression, or a strong predatory drive, represent a much greater risk of showing problem behavior toward children than dogs exhibiting a more calm, playful, and friendly temperament (see *Evaluating the Risk* in Volume 2, Chapter 6).

Socialization

Perhaps the most important single factor influencing an adult dog's positive reaction to a baby or child is a history of positive socialization with children. Couples who plan to have children should make an effort to socialize the young dog with children of various ages. Allowing children to pet quietly and gently or give the puppy food can be very helpful. However, allowing a wild group of screaming kids to mob the puppy is certain to have an opposite effect on the puppy's expectations and future response to such contact, possibly causing it to become fearful of children. Another way to socialize a puppy with children is for the owner to baby-sit, thereby allowing the puppy to interact with children in the context of the home. Socialization experiences of this sort probably benefit the children as well, especially if they do not have a dog of their own, since previous noneventful contact with dogs appears to exert a preventive influence on the development of a fear of dogs by older children and adults (Doogan and Thomas, 1992).

Basic Training and Management

The importance of appropriate obedience training cannot be overemphasized. Basic training is essential, especially in the case of dogs exhibiting impulsive or hyperactive behavior. Dogs showing excitable tendencies should be exposed to intensive attention therapy, recall to front-and-finish, starting exercise, following, controlled walking and quick-sit, off, leave it, back, wait, go-lie-down, and down-stay training. All of these modules and routines should be practiced to a high degree of proficiency in advance of the baby coming into the home. The dog's overexuberance during greetings and full-tilt rampages through the house and garden represent a considerable risk of injury for a baby or toddler.

Managing an overactive dog includes the provision of adequate daily exercise (including walks, jogging, and ball play), basic training, and necessary restraint and confinement (see *Hyperactivity and Social Excesses* in Chapter 5). The skills learned during basic training provide the owner with the means to control the overactive dog effectively in everyday situations. Whether it is done privately or in class, training should be initiated long before the baby's arrival and should continue for several weeks thereafter. Training should include practicing basic exercises while the owner is engaged in activities that mimic actions and situations that are likely to occur with the baby in the home. For example, the owner should have the dog perform exercises such as sit-stay while the owner is holding a doll wrapped in a towel or while rehearsing a diaper change. Also, the dog should be trained to walk next to a stroller until it becomes comfortable with its sound and movement. This should be done before the baby is actually placed inside of it. Practice should include exiting and entering the home, getting into and out of the car, and other likely situations that will regularly occur with the baby and dog in tow. An extremely useful way to enhance control during walks is a hip-hitch with a control lead and fixed-action halter collar. If halter use is planned in the context of introducing the dog to the baby, it should be slowly introduced in association with reward-based training.

A high chair should be set up, with food, bibs, towels, and other items placed upon it that might be present when the baby is being fed. The dog should be trained to avoid jumping up on the high chair in the owner's presence and absence, thus probably requiring some form of appropriate booby trap. Further, the dog should learn not to jump up on people or furniture (bed, sofa, chairs, etc.) without permission, thus preventing potential incidents involving the dog stepping on the infant while he or she is in the mother's charge being fed or changed. An overly active

dog should be routinely constrained to wait outside of the kitchen until released to enter on the owner's signal. If necessary, gates or crate training may be introduced to facilitate a safer transition.

Competition around passageways should be systematically discouraged by training the dog to defer to the owner's entitlement to enter first or to move ahead only if prompted to do so. Similar practice efforts should be carried out around the front door and back door, with bolting being vigorously suppressed with appropriate leash training. The active dog should received focused training around indoor and outdoor steps, learning to wait or to move ahead of the owner on signal, but never charging ahead without the owner's consent. Again, such training efforts as just described should be introduced long before the baby comes into the home.

Exposure, Counterconditioning, and Habituation

Fearful dogs should receive intensive behavioral training and conditioning aimed at increasing their confidence and tolerance toward children and their actions. A fearful dog, appropriately restrained on leash and collar or halter, should be exposed to structured social encounters with children of all ages. During such counterconditioning efforts, the dog is prompted to sit and relax by giving it food and petting while in close proximity with children (see *Social Fears and Inhibitions* in Chapter 3). The owner can also mimic some of the sounds and awkward movements of the baby or toddler. For example, the dog should be exposed to having its ears, tail, and other parts of its anatomy grabbed and gently pulled, thereby simulating the touch and handling of a curious child. Such handling exposure should be performed in association with appetitive counterconditioning or with the dog in a relaxed state induced by PFR training. The fearful dog is gradually exposed to a wide variety of situations involving children both in the home and away from home. Again, babysitting an infant would give the dog a chance to learn about babies, thereby possibly helping to mitigate problems later on. Fearful dogs exhibiting a demonstrated propensity to snap or bite rather than retreat from children should be removed from the home.

Habituating a dog to new sounds and smells associated with a new baby in the home may also be useful (see Appendix C). This ought to include "pretend" activities in which the expectant mother holds a doll wrapped in a blanket while changing it, applying various oils and powders. It is useful to play tape recordings of an infant crying and other sounds occurring during such activities in order to make the situation more realistic. Items imbued with the baby's odor (e.g., clothing or blankets) should be brought home from the hospital in order to allow the dog to habituate gradually to the various olfactory stimuli associated with the infant's presence.

PFR training is a central part of the dog's preparation for the baby's homecoming. The PFR cycle can be carried out with small amounts of the various odors (oils and powders) scenting the owner's hands. As the massage progresses from day to day, the recorded sounds of a baby crying can be played at progressively increasing volumes, emanating from different parts of the house. A conditioned odor [e.g., dilute (1:30–50) orange, lavender, or chamomile] can also be introduced in association with PFR, first introduced as an olfactory signature at the end of the cycle and then using it to help consolidate the relaxation response by presenting it at progressively earlier steps in the PFR process. The massage should result in deep relaxation, at which point the right hand is gently cupped over the dog's nose for a brief moment, causing it to sniff the odor. The dog is petted over its entire body, carefully following the lay of the coat, and, at last, released with a quiet clap of the hands and "Okay." With the baby's arrival, blankets and clothing imbued with the child's scent can be brought home and paired in a similar way with deep relaxation and feelings of comfort.

The dog should be familiarized with the baby's room and permitted to investigate freely, but access to the room should never be allowed in the owner's absence. Booby-trapping the doorway of the baby's room may

provide additional inhibition about entering the room without supervision. Otherwise, the room should always be gated or closed. In general, a baby should never be left alone with a dog.

Establishing a Routine

The owner should establish a daily routine of activities prior to the baby's arrival that reflects realistic estimates of time available to dedicate to the dog when the baby comes home. To ensure a successful transition, this allotment of time should not be significantly changed. The daily schedule should include sufficient time for training, exercise (at least 20 minutes twice a day), and affectionate attention. Daily walks are a good postparturient activity for the new mother as well as a positive activity for the infant and dog. Perhaps even more important than the amount of time given to the dog, the quality of interaction should not be compromised or become superficial. There is a natural tendency to turn affectionate contact away from the dog and to redirect it toward the infant. The ensuing neglect of the dog's social needs for daily affectionate contact may stimulate insecurity and prompt intrusive efforts to gain contact and attention by undesirable means.

INTRODUCING BABY AND DOG

First impressions are lasting. It is imperative, therefore, that the first meeting between the dog and the baby occur without incident. Many techniques are available to help ensure an uneventful introduction. The usual method involves having the mother enter the home *without the child* in her arms. After the initial excitement has dissipated, the dog can be familiarized with various items containing the baby's odor while being fed treats and affectionately petted. After a brief period, the leashed dog can be permitted to sniff the blanket covering the baby while continuing to receive treats.

Whenever possible, however, the baby should be introduced while the dog is preoccupied on a walk away from the property together with the mother and a helper holding the baby. This procedure minimizes a number of natural tensions that are prone to occur if the baby is taken directly into the house, especially in cases involving a dog that is unfamiliar with infants. The most common reaction by far is curiosity, but sometimes the dog is alarmed by the "strange creature," resulting in nervous growling or barking. This is definitely a result that one would wish to avoid. Going for a walk serves to distract the dog from the baby's presence, which is overshadowed by the excitement of being outdoors. Under such conditions, the dog's curiosity and potential anxiety are reduced to a more manageable level. If the dog becomes overly excited, it should be prompted to sit and thereupon rewarded by the owner with affection and food. After the dog has calmed down and settled into the walk, the mother can take the child herself and hand over control of the dog to her helper for the remainder of the walk.

Upon returning to the house, the dog is required to wait before entering, allowing the mother and baby to enter first, followed momentarily by the helper and dog. The leashed dog is permitted to smell the covered child and given numerous treats and vocal encouragement so long as it remains low-keyed and calm. With things going well, the dog may be engaged in normal play and affectionate activities, first with the helper and then with the mother. Lastly, the dog is fed while the mother attends to the baby nearby as though nothing very remarkable has taken place. The leash and collar should remain on the dog during the next few days for added control and safety.

Although every effort should be made to make the transition a positive one, limits should be immediately and clearly set, if necessary, especially in cases were the dog becomes overly pushy or demanding. If necessary, such dogs should be kept on a fixed-action halter for added control and safety. Repeated and brief TO (30 to 45 seconds) with intensive time-in reward training (orienting, attending, sit and down, and stay) can be used to help reduce arousal and impulsiveness. Behavior to be particularly on guard

about involves excessive efforts to poke and smell, jump up, or to grab at the baby's blanket. Such behavior can be discouraged with a split-second hiss with a modified CO_2 pump dry-loaded with a dilute conditioned odor (e.g., cedarwood-eucalyptus). The conditioned odor is delivered with stealth (e.g., under the jaw or from behind) and at pressure appropriate to the dog's response to the hiss-type startle (see *Olfactory Conditioning and Excessive Biting* in Chapter 6). The conditioned odor and modified CO_2 pump can be used to help set limits around undesirable household behavior requiring mild inhibitory conditioning to control. If a modified CO_2 pump is used, it should be introduced in advance of bringing the baby home, giving the dog a chance to become familiar with the treatment strategy.

In some cases, an overly excitable dog can be restrained on a tie-out or active-control line while being introduced to the baby. The mother and child are seated on the floor some distance away while the helper gives the dog treats as the two gradually inch forward in progressive steps toward the dog until they are situated just in front, where the dog receives food and affection from the mother and is permitted to smell the baby's clothing (see *Graded Interactive Exposure* in Chapter 3). An alternative method involves giving the dog a hollow rubber toy stuffed with a piece of bread smeared with peanut butter. During such graduated exposures, the helper can initiate a cycle of massage and introduce odors previously association with PFR training, thereby helping to recruit a relaxation response in association with petting and massage. The conditioned odor can be delivered by means of scented tissue or a squeaker bulb with the squeak valve removed. As the dog calms down, the child's hand can be placed in the middle of the mother's hand and held in front of the dog's nose, allowing it to sniff in association with reassuring talk and petting. This procedure is repeated several times and then as needed to relax the dog when it becomes overly excited.

Another strategy involves having the dog live somewhere else temporarily and then to habituate it slowly to the presence of the child over the course of 2 or 3 days. Initially, the owner can spend time with the dog alone, reviewing obedience work with a doll wrapped in the baby's clothing, either carrying the doll or pushing a stroller. These practice sessions can be followed by controlled meetings between the dog and the baby, at first outdoors and then inside the home. A conscientious effort should be made to establish positive associations with the baby's presence, including the provision of affection, treats, toys, and other sources of pleasure for the dog. Ideally, the dog should learn to anticipate attractive and pleasurable outcomes whenever the baby is brought into its presence. Although temporarily housing the dog elsewhere is sometimes very useful, it is far better not to remove the dog from the home situation, but to make the necessary arrangements and efforts to work things out while the dog remains in the home.

The Toddler and Increased Risk

As the child becomes ambulatory and begins to explore the dog with clumsy hands and awkward movements, new opportunities for disaster inevitably follow. Naturally, with the advent of such increased interaction, a greater risk presents itself that the dog will resent such contact or become progressively intolerant of it, possibly resulting in aggressive threats or snaps. Dogs that are possessive toward food, toys, or places are particularly dangerous around toddlers. Not surprisingly, toddlers are a common target of aggressive attacks, with boys being bitten much more often than girls (Harris et al. 1974; Wright, 1991). This difference may be attributable to the male child's greater tendency to engage in risk-taking behavior (Ginsburg and Miller, 1982). Another possible explanation is that boys may simply spend more time interacting with dogs than girls do (Lehman, 1928). Dogs exhibiting irritable or possessive aggression toward the child should be removed from the home.

The most significant threats at this age are generated by the child's failure to recognize and respect the dog's needs for space and gen-

tle handling. Although children exhibit increasing evidence of empathy by years 3 and 4 (Love and Overall, 2001), the display of these sensitivities is not particularly evident in the relentless teasing and torment that a young child can inflict upon the family dog. Children aged 2 to 3 appear to exhibit the highest frequency of provocative behavior toward dogs, making close supervision of child-dog interaction especially critical during this age period. Children aged 4 to 5 exhibit less provocative interaction and make more comforting-giving tactile contact with the dog (Millot and Filiatre, 1986). In any case, allowing the child to taunt, grab, pull, pinch, step on, chase, throw things at, hit, kick, stomp, or fall upon the dog is a sure way to increase irritability and reduce tolerance for close social contact with the child. Every normal dog has a breaking point that is sooner or later reached, and the child is finally punished for his or her lack of consideration and sensitivity.

Many problems can be avoided by making sure that the young child is allowed to interact with the dog only while an adult is present to supervise, at least until the child demonstrates an adequate ability to treat the dog with care and respect. During such periods of supervised interaction, the child's behavior is carefully monitored, with appropriate behavior being reinforced with affection and other suitable rewards, while inappropriate behavior is consistently discouraged. The child should be taught that interacting with the dog is a privilege based on good behavior. One strategy for promoting this learning involves giving the child merits for appropriate interaction and demerits for inappropriate behavior toward the dog. The accumulation of three demerits causes the child to lose the privilege of interacting with the dog for some set period. The child can avoid this consequence by working off demerits by earning merits based on appropriate behavior. In other words, demerits can be canceled by earning merits based on giving the dog appropriate care and respect. In addition, after earning three merits, the child may be given a token (e.g., a star) that he or she can save and exchange for various rewards or desirable activities.

Child-initiated Aggression and Sibling Rivalry

Within the context of family dynamics, emergent canine behavioral characteristics (individual differences) are differentiated and expressed, giving rise to an extraordinary variety of social behavior and coping styles. In large families, preferred affiliative relations may form that produce conflict and competition between children for a dog's attention. Some of these attachments and affiliations appear to promote distinctions resembling social rank. The dog may show favoritism toward certain family members and become progressively intolerant of interaction with others. Much of this organizing process is based on the quality of the exchanges and transactions between the dog and different family members. Transactions conducive to enhanced comfort and safety are preferred to transactions producing discomfort and threats. The obligatory subordinate status of dogs is dependent on leadership (see *Dominance, Social Distance and Polarity, and Begging for Love*), that is, structured interaction that results in enhanced comfort and safety (nurturance). In relation to other obligate household subordinates (dogs and children), the dog may form dominant-subordinate sibling relations. The nature of these sibling relations and dynamics may be in part due to competition for the same social resource, that is, the nurturance and security provided by the parent. As a result of combined needs that exceed the parent's ability or willingness to fulfill, a potential source of conflict between the dog and children may develop and result in sibling rivalry. This natural sibling tension may be intensified significantly in cases where the parent shows an evident preference toward the dog by the quality of attention and care given to it versus the child. The added attention given to the dog may inadvertantly establish a problematic alliance between the parent and the dog, perhaps activating species-typical agonistic scripts and competition between the dog and children.

Typically, dogs are enormously tolerant of child-initiated interactions, most often ignoring or reciprocating in kind (especially with regard to friendly and comfort-giving behav-

iors), or retreating in response to aversive or aggressive behaviors. Millot and colleagues (1988) found that the aggressive behavior initiated by a child toward a dog was most likely followed by retreating or avoiding behaviors. The most likely child behaviors to produce biting or attempts to bite were pulling the dog's tail, fur, or paws. Dogs were found to be surprisingly tolerant toward threatening, hitting, or object-throwing behavior. Interestingly, dogs exhibited no aggression toward children interfering with them while in possession of objects, but were most likely to give the object up or retreat. The researchers suggest that much of the child's aggressive behavior toward the dog *could be* of a redirected nature. Such child-initiated aggression toward the family dog may reflect a more general failure of the child to integrate friendly and cooperative social relations with peers and adults. Thus, the dog may represent to some children a relatively safe object for discharging frustration and passing on aggression received from other children or adults (see *Sources of Conflict and Tension Between Children and Dogs* in Volume 2, Chapter 6). Children suspected of showing such behavior need to learn how to cope more effectively with social stressors and how to redirect their aggressive impulses into more constructive outlets. A small percentage of children who are persistently provocative and cruel toward the family dog and other animals may be affected by disturbances impeding their ability to regulate emotion and aggressive impulses. Approximately 2% to 9% of children in the United States are affected by conduct disorder. Some authorities estimate that 25% of these children show cruelty toward animals and that animal abuse is often the earliest sign of the disorder (Miller, 2001). Inculcating a caring and humane attitude toward dogs and other animals should be a central part of childhood education and socialization.

Interspecific sibling rivalry and competition for parental attention and care may also represent a significant source of agonistic tension between children and dogs. How children respond to sharing the home and parental attention with the dog depends on a wide range of emotional, behavioral, and developmental variables. Children may show a highly ambivalent and conflictive attitude toward the dog. Young children often show inconsistent social interaction toward the dog, including elements of affection, intrusive interference, and exploitive mischief. In many cases, these behaviors appear to be calculated to obtain or to divert parental attention and resources away from the dog. For emotionally secure children, the dog may mediate a more mature and cooperative relationship with the parent and other siblings. Such children may take an active role in training and caring for the dog; that is, they help to parent it. Other children may show a variable lack of interest or an apparent aversion toward it (e.g., an inordinate disgust toward its saliva). Such children may form a relationship with the dog only to please the parent, but secretly hold the dog at a distance emotionally. Some children may be highly critical of the dog's habits and intelligence, refusing to form a relationship with it and rejecting efforts to help bridge the gap. Finally, a small minority of children may exhibit an overt and habitual pattern of insensitivity, cruelty, and stimulation-seeking activities that may include agitating or tormenting the dog.

Dogs shown preferential treatment by adults in the household may become increasingly confident and bold with respect to sibling subordinates. Instead of fleeing to avoid the interference of children, they may simply confront and threaten them fearlessly. Such dogs may show a high degree of social competence and purposefulness in the process of setting limits on the intrusive behavior of children. They may show a welcoming tolerance for interaction that is gentle and respectful, but rapidly respond to mishandling or uninvited intrusions by stiffening, growling, snarling, snapping, or biting the child to impress their point. Mishandling and interference with the dog while it is eating, resting, or chewing on toys may significantly decrease the dog's tolerance for contact and lower aggression thresholds. Clumsy and painful efforts to pick up the dog as a puppy may also play a prominent role in the development of preemptive threats and attacks to hugs and

grabbing movements. Such dogs may show little sign of anxiety or active aversion toward the child, but instead seem to use aggression in a proactive way to limit unwanted social behavior and rewarding appropriate behavior with affectionate tolerance.

The selectiveness, purposefulness, coolheaded, and limited nature of these confrontations and limit-setting actions is consistent with a social-training interpretation, insofar as social training is defined as a process whereby limit-setting actions serve to open a social space within which appropriate behavior is encouraged by reward. The adaptive and measured nature of such attacks warrants the term proactive aggression. In some cases, however, successful control of one family member with threats or force may lead to dynamic changes in a dog's interaction with other family members belonging to the subordinate-sibling group (see Chase et al., 2002). Other family members observing these educational transactions may exhibit an increased sensitivity and avoidance of exchanges that might agitate the dog, thereby learning from the demonstration and reinforcing the dog's trainer role. Smaller breeds expressing medium anger and high fear thresholds may be particularly prone to exercise social power of questionable competence by means of threats and inhibited bites directed against intrusive children. Although the danger of such behavior would naturally rise to an entirely different level of significance and concern in the case of larger dogs or dogs showing impulsive aggression, the diminutive aggressor may enjoy a special status and alliance with a parent, who may grant "training" privileges to the dog with respect to an unruly child. To prevent the escalation or transition of the "trainer" script into the despot script and interaction that poses a much greater risk to the child's safety, it is imperative that dogs and children learn from parents how to respectfully interact one another.

In addition to procedures used to organize the social engagement system (orienting, approaching, and attending) (see *Dominance, Social Distance and Polarity, and Begging for Love*), preliminary testing suggests that the model/rival method may be useful in certain cases to help integrate more friendly interaction (see *Rapid Complex Social Learning* in Chapter 10). By allowing dogs to observe highly formalized and friendly exchanges between a parent and child (model/rival dyad) with exchanges focused on an object of significant interest to the dog, some dogs appear to rapidly encode the general significance of the observed interaction and show immediate behavior remarkably consistent with it. While observing such brief social encounters, dogs may internalize the emotional significance of the interaction, appearing to prepare them to respond to the object and the model/rival demonstration in a script-consistent way. Dogs appear to be highly sensitive to the significance of social interaction between a social superior and inferior (rival) in the process of obtaining reward or punishment in the context of controlling a valued object. The full value of the method remains to be explored, but preliminary indicators suggest that the effect produced is robust and useful as an adjuvant procedure for priming emotional arousal and rapidly integrating social scripts. In addition to modeling affectionate behavior and cooperative behavior, the procedure may have usefulness for treating object-guarding problems and for helping to mediate the integration of more tolerant and friendly behavior toward visitors.

Impulsive, Extrafamilial, and Intraspecific Aggression

PART 1: INTRAFAMILIAL AND EXTRAFAMILIAL AGGRESSION

The care and training received by dogs with aggression problems is frequently not much different from the treatment received by dogs that do not develop aggression problems. Why one dog is friendly and another dog aggressive when both grow up in the same household is only an enigma to the extent that one assumes that the needs of the two dogs are the same. This underappreciation of the diversity of canine individual differences and needs for individualized socialization and training has led to considerable confusion and mismanagement of dogs. The interactive and environmental needs of dogs vary considerably, not just between breeds, but also between individuals of the same breed. What for one dog may promote a secure attachment, for another may represent an intolerable situation facilitating ambivalent social and place attachments. The obvious implication with regard to the prevention and treatment of aggression problems is that dogs require socialization, training, and quality-of-life enhancements that are tailored to meet the dog's particular needs.

As argued in Chapter 7 and expanded upon below, the social dominance hypothesis does not appear to have much value for understanding and treating most intrafamilial and extrafamilial aggression problems. Several features of canine domestic aggression (CDA) conflict with the dominance hypothesis, including the incompetent and insecure nature of attacks; the antecedent activities and situational peculiarities leading up to attacks; the panicogenic, catastrophic, and paroxysmal nature of arousal associated with attacks; the reactive negativity bias shown toward ambiguous social signals given by persons intimately familiar to the dog; and the terrified appearance of aggressors at the flash point of attack. Diagnosing such behavior as dominance aggression seems akin to tossing a pig in the air and claiming that pigs can fly. Although dominance relations in the organization of dog behavior are not entirely trivial, especially as regards interdog relationships and the setting of social limits on undesirable behavior,

dominance as a proximal cause of reactive and impulsive aggression appears to be little more than a narrative account with little substantive value as a causal concept. The dominance diagnosis appears to be more relevant to how humans cope with dog bites and canine misbehavior in general than to the etiology and rational treatment of aggression problems.

Anthropic dominance ideation converts intrafamilial and extrafamilial CDA into a form that absolves the victim from responsibility while demonizing the canine aggressor with despotic social or territorial intent, thereby justifying abusive appetitive and emotional deprivation, stressful isolation tactics, and physical maltreatment in the name of canine behavior therapy aimed at changing the dog's dominant attitude (see Bugental et al., 1997 and 1999; also see *Anthropic Dominance Ideation, Perceived Power, and Control Styles* in Chapter 10). Far from the confident picture that one might expect from a dominant dog, many of these so-called dominance aggressors appear to be socially incompetent, insecure, and reactive in their dealings with people. In severe cases, just before attacking, impulsive aggressors appear to be overwhelmed by intense sympathetic arousal that seems foreign to the dog and inappropriate to the evoking stimulation. Although impulsive aggression has been linked to seizure activity (see *Epilepsy* in Volume 1, Chapter 3, and *Assessment and Identification* in Volume 2, Chapter 8), most authorities currently downplay the seizure hypothesis. Although limbic seizure and a host of other biogenetic and neurobiological factors (e.g., serotonergic/dopaminergic imbalance) appear to contribute in various ways to the expression of aggression, very little clinical or experimental evidence points to any single variable or set of variables as a cause of aggression.

Autoprotective aggression can occasionally be traced to specific abusive or traumatic experiences. In one such case, a woman with a psychotic condition obtained a puppy as a companion after her release from a state psychiatric hospital, where she had apparently resided for several years. According to reliable witnesses, the woman came outside at various times during the day to sit on the stoop and affectionately stroke the puppy and fuss over it with sweet talk. For unknown reasons, the woman periodically became enraged and would turn without warning and slap the puppy forcefully along the side of its head, whereupon she would appear to be very sorry for the action and attempt to comfort the puppy with petting and other expressions of affection and comfort giving. As the puppy calmed down, the woman would again, for no apparent reason, turn and forcefully hit the puppy, causing it to yelp in distress. This ritual was observed on several occasions and prompted neighbors to take action to rescue the puppy. It was adopted and raised successfully without notable adverse signs of the abuse from its experience until approaching adulthood, when it began to bite visitors in a very odd way. During greetings, the dog showed very friendly behavior and quickly warmed up to visitors and accepted their petting without any sign of resentment or fear. But suddenly, and without warning or provocation, the dog's demeanor would rapidly change from affection to rage and, in an instant, it delivered hard bites to hands as it was petted about the head. The aggression was limited to visitors with whom the dog had formed some degree of affectionate contact, and the attacks occurred only while the dog was being petted. The dog had an affectionate and nonaggressive relationship with a caring and protective owner. The bizarre attacks were otherwise inconsistent with the dog's temperament and by observation could not be guessed from any behavioral signs. The etiology of this bizarre and dangerous aggression appears to have stemmed from the abusive unpredictable and uncontrollable handling that the dog was exposed to as puppy, perhaps resulting in the formation of toxic expectancies in association with petting. While initially accepting the visitors' petting, as the interaction continued an apparent internal conflict emerged that rapidly escalated into a fearless panic-type attack. One is tempted to interpret the aggression exhibited by the dog in terms of a collision of affection, a toxic expectancy formed in puppyhood, and a sudden loss of safety and trust, resulting in the release of an angry hard bite. The owner

may have been protected from such attacks by having formed a trust-based bond with the dog reinforced by a history of safety in the context of affection (see *Contact Aversion and Aggression* in Volume 2, Chapter 8).

In addition to etiologies associated with abuse, aggression problems appear to be related to less obvious biogenetic and epigenetic causes (e.g., exposure to prenatal stress) that are incubated by social exchanges promoting a negative coping style. According to cynopraxic theory, neurobiological systems are malleable and adapt in response to both positive and negative adjustment pressures, making selective attention and behavior the axial conduit for the mediation of both disturbance and therapeutic change. The neural plasticity resulting from cynopraxic attention and behavior training serves to entrain compensatory neural and physiological changes in the process of integrating social skills, adaptive coping style, and secure attachments. These neurobiological changes are hypothesized to promote autonomic, cognitive, and emotional regulation conducive to enhanced attention, impulse control, and calming. More specifically, with respect CDA, cynopraxic therapy facilitates the acquisition of cognitive and behavioral skills incompatible with aggression by arranging conditioned and unconditioned stimuli, social exchanges, and environmental enhancements to promote autonomic attunement and affectionate play. As such, the executive attention and impulse-control deficits, emotional distress, and autonomic disturbances associated with a reactive coping style and aggression are interpreted as flowing from social interaction and home environments promoting ambivalent (nervous/insecure) attachments. The integration of secure social and place attachments via cynopraxic therapy promotes social trust and autoattunement, enabling dogs to form social bonds and to explore new social relations competently and novel environments under the regulatory control of enhanced sympathovagal balance.

CLASSIFYING AGGRESSION

In general, proactive control-related or instrumental (offensive and defensive) aggression is organized to achieve specific goals not otherwise achievable, showing the following characteristics: (1) a relatively consistent ensemble of sequential events and junctures (i.e., transitional points leading to escalation or de-escalation of hostility based on control-related outcomes) that move predictably from agonistic arousal, precursor intention movements, ritualized threats, and formalized interaction (e.g., exchanges and transactions) conducive to conflict resolution and subsequent reconciliation or, in the absence of alternative options, conclude with a moment of menacing suspense and overt confrontation/attack; (2) a demonstrated ability to escalate, de-escalate, or cancel agonistic processing at any juncture in the formal sequence of events; (3) a concordance or context appropriateness between the provoking situation, the trigger, and the magnitude of arousal and attack (i.e., severity and duration); (5) a functional significance [e.g., an offensive response to promote control interests (i.e., get-and-keep incentive) or a defensive response to aversive stimulation or an imminent threat of same (i.e., bite-or-die incentive) and responsiveness to outcomes (e.g., suppression by defeat); and (6) rarity (see Smith, 1977). Instrumental attacks may take a more confrontational and direct form (without much warning) in the context of social code violations (e.g., threatening to take a prized item and disturbing a sleeping dog), but such attacks (nips and snaps) remain inhibited and appropriate to the evoking situation.

In contrast, reactive or impulsive autoprotective aggression shows a lack of competent sequential organization, with antagonistic arousal rapidly transitioning into a default attack mode that is often severe, uninhibited, out of character, and disproportionate to the provoking social context. Impulsive attacks tend to increase in frequency and severity over time, suggesting a process of progressive disinhibition influencing the expression of such behavior. Twelve prominent independent variables appear to play important roles in the etiology of reactive/impulsive autoprotective aggression: (1) genetic predisposition; (2) developmental adversity (prenatal, perinatal, and postnatal stress and insults); (3) interac-

tive disturbances impairing executive attention and impulse control; (4) lack of competent social coping skills and play; (5) persistent interactive conflict; (6) social ambivalence (distrust and unfairness) in association with growing anxiety, irritability, and intolerance; (7) a history of mismanaged competition and proactive aggression; (8) a reactive trigger formed in association with loss or risk; (9) the presence of nervous/insecure social and place attachments; (10) loss of trust and autonomic attunement; (11) deprivational environmental conditions; and (12) entrapment.

An aggressive dog's appearance of aloofness, inattention to social signals, insular resistance to owner control efforts, reduced playfulness, and arbitrary threats and attacks are frequently viewed through the distorted and pseudoscientific image of the "alpha wolf" and other prominent ethological myths. According to cynopraxic theory, the social withdrawal and tuning out of an ambivalent attachment object is not indicative of dominance, but rather represents a gradual process of social and attentional disengagement in anticipation of reduced impulse control and increasing social repulsion and intolerance. Under the inescapable conditions of domestic life, dogs are compelled to cope and adjust to the social and environmental circumstances that they find, since leaving the situation is not a viable option. Domestic situations lacking sufficient fairness, order, and resources to meet basic canine social and biological needs pose special challenges. Dogs cope with adverse and inescapable household conditions in three principal ways, depending on perceived controllability and fairness: (1) Households and interaction perceived as being relatively uncontrollable and deprivational promote a reactive coping style and autonomic regulation conducive to nervous attachments. (2) Households and interaction perceived as being relatively controllable and providing for basic needs, but unfair and enabling or coercing dependency by means of indulgence and/or subjugation, tend to promote insecure attachments. (3) Households perceived as being relatively uncontrollable, deprivational, and unfair facilitate autonomic shifts and dysregulation, making the ambivalent attachment object a target for reactive or impulsive autoprotective aggression.

In addition to conditioned aversive associations stemming from interactive conflict, a major source of anxiety and anger is related to the motivated disengagement of attention and social resources from an ambivalent attachment object. As such, the *anxious anger* of social ambivalence is an amalgam of anxiety and anger fused under the escalating tensions of entrapment and autoprotective motivations evoked by interaction perceived as inconsistent, unfair, and inescapable. Social ambivalence and entrapment dynamics are hypothesized to promote reactive and impulsive behavior flowing from the gradual or precipitous disengagement of attentional and social resources in the process of degrading impulse control and autonomic/emotional regulation. Increased anxiety and reduced impulse control are the natural corollaries of diminished selective and sustained attention. The anxiety component of social ambivalence is hypothesized to infuse ambivalent exchanges with distrust, whereas the anger component of social ambivalence, flowing principally from the retraction of the social engagement system in response to anxious and unfair exchanges, generates social repulsion, irritability, and intolerance.

The net effect of social ambivalence and entrapment is to install a preemptive negativity bias consisting of distrust and intolerance, altering the way the dog perceives, interprets, and responds to exchanges with the ambivalent attachment object. Autoprotective or exploitative (antisocial) behavior shown in response to ambiguous actions and unexpected change reflect a negativity bias and autonomic misattunement, whereas prosocial behavior in response to ambiguous actions and unexpected change reflects a positivity bias and autonomic attunement. Whereas incompetent reactive or impulsive dogs may respond to ambiguous social exchanges as signifying a threat of loss or risk, dogs operating competently under the regulation of secure attachments tend to approach ambiguous situations confidently with an anticipation of fair exchange and reward.

Antipredatory Strategy and Autoprotection versus Dominance

Dogs that fail to attract, attach, and please human companions prove too expensive or inconvenient, or otherwise become undesirable or unwanted as pets are at risk of being relinquished, concentrated in shelters, and destroyed if no one takes an interest in forming an attachment with them. The millions of dogs killed every year is stark evidence of the human appetite for the pleasures of canine companionship and the default lethality awaiting dogs that fail to provide it. Among the Romans, unwanted infants were often left to die in a public place unless a passerby happened along to rescue them, a practice that frequently resulted in the children becoming slaves. The foregoing practice of infant exposure seems to roughly prefigure the modern-day function of the shelter whereby dogs that are no longer wanted are relinquished, put on public display, and subsequently killed if they fail to inspire sufficient attraction or pity to integrate an attachment. The act of relinquishment allows owners to seek a more gratifying pet while separating themselves from the unpleasantness of disposing of the unwanted one. The subsequent killing of the unwanted dog makes room for more dogs, thereby perpetuating the cycle of extracting affection and submission from the canine attachment object and destroying those that fail to provide it. The pattern of taking an infant puppy away from its biological family, subjugating it by force and restraint, abandoning or relinquishing it, and destroying the dog when it is no longer wanted represents a pattern of exploitation that infuses the human-dog relationship with an inherent paradox (Tuan, 1984; see *Yi-Fu Tuan* in Volume 1, Chapter 10). The predatory exploitation of the dog for its fur and flesh is sublimated and institutionalized into a less obvious predatory preoccupation with the exploitation of its capacity to provide affection, submission, and utility. As such, the dog is transformed into a prey object whose ability to gratify human needs depends on it staying healthy and alive, at least during times of plenty. These predatory pressures centering on the human appetite for affectionate companionship and dominion have selected for traits compatible with taming, social submission, and training, while simultaneously suppressing canine predatory propensities and behaviors.

As an object of human attachment and domination, a dog is spared from the knife and fork but not from cruelty and death if it fails to yield the social resources for which it is spared and upon which its protected status depends. Under these sorts of life-and-death pressures, it is reasonable to expect that dogs might have evolved various complementary antistress and antipredatory coping strategies to reduce the risk of human exploitative appetites and abuses. Dogs appear to have evolved an ability to integrate secure attachments that mediate autonomic regulatory changes in their human keepers. The dependency and insecure attachment produced by indulgence and domination is hypothesized to combine with affectionate submission and begging to facilitate parental-like care and protectiveness, the secure feelings of unconditional acceptance, and, potentially, the joy of affectionate play. These emotional and behavioral effects of autonomic attunement may help to ensure that keepers will not decide to abuse, eat, abandon, or kill their dogs. The dog's neotenous appearance, soft fur and appreciation of petting, and the giving of unconditional acceptance to the keeper may be important positive antipredatory adaptations that further enhance attachment-mediated autonomic control. However, in response to ambivalent attachments and entrapment, negative antipredatory survival modes may be activated in the process of lowering autoprotective flight-fight thresholds. Historically, at times of dearth, dogs may have lost their protected status, just as today dogs are at an increased risk of relinquishment and death if they become inconvenient or too costly to maintain. As a result, indicators of reduced parental investment (social attention and care) and resource availability appear to activate additional antipredatory survival modes that increase avoidance and dispersive tensions. The dog's apparent sensitivity to social and environmental quality-of-life changes, as indexed by changes of affiliative receptivity,

dispersive tensions, and altered flight-fight thresholds, is consistent with the activation of encoded survival modes responsive to changes likely to anticipate a change in predatory risk.

Despite the evolution of a specialized antistress system for coping with ambiguous, novel, and unexpected events, dogs appear to be especially vulnerable to show reactive behavior at times when selective attention is disengaged. For example, disturbing a dog while it is asleep has been associated with fierce attacks that have confirmed the wisdom of the proverb "Let sleeping dogs lie" countless times (see *Aggression Associated with Disturbances While Resting* in Chapter 7). The dog's love of sleeping in close company with humans, especially on the bed, and the immense enjoyment that many people derive from sleeping in close quarters with a dog may point to an important adaptation having ancient origins, perhaps helping to keep many dogs out of the communal pot. Sleeping with dogs may have provided ancient dog keepers with feelings of enhanced security and comfort (see *The Dingo: A Prototypical Dog* in Volume 1, Chapter 1). These comfort-enhancing benefits may have been especially important resources for the young, sick, frail, or elderly, perhaps providing an interesting account for the evolution of traits conducive to a natural sense of compassion and gentleness. Instead of preying on the weakness of such people, dogs often show them special treatment—behavior that is commonly extended to young children, as well. During the dog's evolution, it has shed most of its predatory instincts, in the process acquiring traits conducive to forming a symbiotic mutualism with human guardians. Essentially, the domesticating process has transformed the canine predator into a predatory object dependent on the subjugating predator for care and protection. Within the context of these evolutionary developments and trends, the notion that dogs might have evolved a set of complementary or antithetical antisocial and antipredatory tactics to cope with the uncertainties and risks associated with living with a predator represents a plausible hypothesis. The reactive and impulsive nature of CDA seems to have far more in common with an antipredatory coping strategy (Kavaliers and Choleris, 2001) than it shares with the idea that dogs attack people to enhance their social status or defend their territory, something that they may do with conspecifics but not with human subjugators. Just as a prey animal may seek to avoid predators by reducing activity and limiting the time it spends in open spaces, the autoprotective orientation shown by many dogs may stem from an analogous antipredatory strategy activated in the context of home situations perceived as unsafe and unsatisfying.

Dogs appear to survive under domestic conditions by means of forming attachments facilitated by affectionate play. According to this hypothesis, affectionate play transactions integrate an autonomic attunement in humans that is conducive to a state favorable to alloprotection and caregiving, perhaps offsetting human predatory interests and power-dominance motivations toward the canine attachment object. The autonomic attunement associated with reciprocal affectionate play exchanges between the dog and human predator promotes social trust and bonding in support of the continuation of affectionate playfulness and the integration of harmonious social relations and mutual appreciation. In addition to secure attachments and the autonomic attunement facilitated by affectionate play, the human-dog bond appears to depend on predictable and controllable exchanges giving mutual advantage via enhanced comfort and safety (security). Canine social trust appears to depend on a fair balance of advantages given and advantages taken in the process of obtaining comfort and safety. An appreciation of fairness appears to emerge in the context of play, since, in the absence of parity, play stops or becomes increasingly exploitative and cruel. Affection is motivationally incompatible with cruelty and, in combination with play, promotes fairness and harmony in human-dog relations. Insecure attachments based on relatively consistent but unfair interaction promote social dynamics conducive to a loss of trust and increased reactivity toward ambiguous social exchanges and unexpected change. Social exchanges that give excessive advantages to the dog, or unfairly force the dog to yield advantages to

the human controller, mobilize disruptive social dynamics that impair affectionate play and bonding. For example, dogs that unfairly receive advantages by indulgent treatment may become increasing dependent and form an expectancy of interaction that is narrowly focused on receiving rather than yielding advantages. In contrast, dogs from which unfair advantages are taken may become increasingly unwilling to yield to exploitative control efforts. In both cases, the dog's ability to trust is reduced, along with social attraction and its ability to play, thereby setting the stage for social repulsion, irritability, and contact intolerance, and activating antipredatory coping strategies and autoprotective behavior in response to human exchanges perceived as posing a predatory threat. In contrast to the playful and cooperative response to human control efforts by dogs expressing secure attachments, dogs expressing insecure attachments show increasing rigidity in response to human control efforts. Similarly, nervous attachments formed in association with exploitative play and inconsistent and manipulative exchanges that evoke anxiety (lack of security) and anger (lack of attraction) keep the social engagement system off-line while mobilizing a variety of antipredatory autoprotective behaviors in response to human control efforts.

The intolerance for physical handling, restraint, and interference that reactive and impulsive aggressors show is consistent with an antipredatory function. These dogs may show tolerance for close proximity and petting but deliver severe and uninhibited bites if picked up. Many dogs reach the flash point of no return only after struggling unsuccessfully to break free from restraint or coping with abusive punishment. Under the influence of inescapable social anxiety and irritability stemming from interactive conflict and ambivalence, the home or areas within it may become more generally associated with entrapment and frustrated dispersive tensions evoking highly motivated autoprotective behavior toward family members. Reactive dogs frequently show aggressive behavior in response to unwelcome grooming, under the influence of an obvious autoprotective incentive. Such dogs may snap if their paws are touched, and become particularly reactive and dangerous if the owner attempts to trim the nails. Again, consistent with the antipredatory hypothesis, some dogs will bite only if grabbed or reached for after fleeing to cover behind a sofa, inside a crate, or under a bed or table, appearing to attack after an intensification of aggressive arousal triggered by entrapment and autoprotective panic. The relative amount of reactive arousal shown by dogs toward ambiguous or threatening social stimuli under such circumstances appears to index social attraction and trust rather than social status or a perception of rank.

Ambiguous activities, such as abruptly crouching down and kissing or caressing a sleeping dog around its muzzle, may stimulate sensations interpreted by the dog as an attack. Attacks at such times are often severe and damaging, followed by pronounced signs of emotional distress consistent with remorse. Dogs may be particularly vulnerable to such attacks when falling asleep (hypnagogic) or awaking (hypnopompic). The vibrissae provide autoprotective sensory information relevant to the detection of objects coming in contact with the face. For example, brushing the canine vibrissae evokes nonhabituating defensive blinking. Also, when making an angry pucker, the vibrissae are turned out and forward. These reflexive effects suggest the possibility that vibrissal stimulation around the face may trigger autoprotective sensations or threatening hallucinations (preemptive processing) when other sensory and attentional resources are off-line. Dogs dream, and these dreams often have sequences that involve apparent efforts to run away or attack an adversary. When startled from sleep, the imaginal content of these dreams may continue during hypnopompic transitions while a dog is awakening. The nature of dream images and their emotional significance may distort how the dog perceives and interprets the owner's actions. Further, during hypnagogic transitions between wakefulness and sleep, dogs may be vulnerable to disinhibited attacks in association with reduced attentional resources and impulse control.

Among human subjects, vague feelings of someone in the room or hallucinations of being attacked or experiencing terror (e.g., falling into an abyss or being caught in a fire) while transitioning in or out of sleep have been reported (Ohayon, 2000). In an urban population, violence in association with sleep and hypnagogic and hypnopompic hallucinations were found to be more prevalent among persons diagnosed with post-traumatic stress disorder (PTSD) than subjects not diagnosed with PTSD (Ohayon and Shapiro, 2000). Consequently, the possibility of a history of abuse or trauma should be evaluated in dogs exhibiting reactive explosive behavior when disturbed while sleeping or resting (hypnagogic). Reactive behavior in response to minimal provocation may be associated with the hair-trigger activation of dysregulated sympathetic circuits. The signal triggering the event may be arrhythmias or the abrupt withdrawal of vagal tone (e.g., when the dog is disturbed while resting) and the provocation of a potent sympathetic surge (see *Autonomic Arousal, Heart Rate, and Aggression* in Chapter 6). Such sudden surges of arousal may induce widespread disinhibition. Ascending signals may kindle stress-sensitized amygdalar or hippocampal circuits, perhaps resulting in reactive attacks (Pontius and LeMay, 2003). The canine amygdala is highly sensitive to kindling effects, resulting in pronounced cardiovascular changes as well as neck and jaw movements (Thompson and Galosy, 1983). In many of these cases, dogs also show autoprotective behavior in response to interference while in havens of comfort and safety while fully awake. Autoprotective behavior at such times may only rise to the level of crankiness and low-grade threats; in other cases, however, it might rapidly transition into a strong threat or attack. These variations in magnitude and severity suggest that trait anger may contribute to an increased propensity for such reactive behavior. A possibility exists that autoprotective aggression in association with sleeping and resting areas may stem from reactive arousal originally evoked in association with being awakened and then subsequently contextualized to the situation and associatively linked to the person. This could help to account for some cases involving inappropriate and explosive aggression near resting places in response to minimal provocation. It is interesting to speculate that during periods of increased social and environmental stress the dog's sleep may be agitated and susceptible to reactive adjustments in response to being awakened. The aversive emotional arousal and reactive behavior evoked at such times might facilitate conditioned social and place associations that may increase the dog's reactivity in the future when disturbed while in such resting places. The liability to develop this behavior may be especially problematic for dogs that have not had time to form competing expectancies incompatible with aggression. These observations may have relevance for understanding the odd finding reported by Guy and colleagues that suggests that puppies allowed to sleep on beds during the first 2 months had an increased risk of developing an aggression problem. In addition, given the disruptive influence of rehoming on previously established attachments and autonomic attunement, puppies may be vulnerable to integrate insecure attachments when allowed to sleep in the bed during the first few weeks.

Whether autoprotection takes a defensive or offensive (confrontational) form is determined by the presence or absence of anxiety/fear (defensive) and anger/frustration (offensive) (see *Species-typical Defensive and Offensive Aggression* in Chapter 7). According to the antipredatory hypothesis, the defensive form of autoprotective aggression is shown reactively toward familiar and unfamiliar targets in response to interaction perceived as posing an inescapable threat. In contrast, the offensive form of autoprotective aggression is impulsively directed toward familiar targets perceived as posing an unappeasable or uncontrollable challenge. Whereas autoprotective defensive arousal is activated by the uncertainty evoked by social novelty or unexpected change, familiar persons and household members with whom the dog has formed nervous attachments via interaction lacking consistency may evoke conditioned autoprotective arousal in conjunction with the disengagement of attention (anxiety), dispersive tensions, and entrapment. In the

absence of attachment relations, vigilance may represent a tactic used by reactive dogs to regulate autonomic tone to establish a state of readiness while simultaneously postponing action. In the case of nervous attachment objects, the withdrawal of attention by the reactive dog is hypothesized to occur primarily as the result of a perceived lack of predictability or relevance informing the object's exchanges. Attentional disengagement from a nervous attachment object is believed to increase social anxiety and decrease impulse control via the withdrawal of parasympathetic tone. Autoprotective offensive behavior, on the other hand, appears to develop in association with insecure attachments or secure attachments that have been disconfirmed and disrupted by a loss of trust and the autonomic dysregulation resulting from social disengagement (anger), motivated inattentiveness (anxiety), social ambivalence, and entrapment. Whereas autoprotective defensive behavior is primarily dedicated to reactive coping with risk, autoprotective offensive behavior is primarily dedicated to impulsive coping with loss. Finally, autoprotective panic—a catastrophic or explosive state of aggressive arousal—is triggered by social interaction simultaneously evoking both loss (anger) and risk (anxiety) occurring in the context of reactive adjustments to social challenges or threats.

Entrapment appears to switch the dog motivationally from a flight mode to an autoprotective fight mode. Punishing the dog beyond the first sign of appeasement, or pursuing it into safe refuges and denying it the ability to obtain comfort and safety (entrapment), represent critical interactive changes that escalate autonomic and emotional arousal and cause the dog to shift the motivational direction of autoprotective behavior away from flight to turn and confront the threat with aggression. The autonomic and emotional regulation and arousal profile concurrent with the relaxation phase of escape to safety appears to be qualitatively similar to the autonomic and emotion arousal evoked by safe havens (e.g., resting on a sofa or bed). Safe refuges and havens (secure place attachments) evoke autonomic relaxation and feelings of enhanced security (comfort and safety). The antipredator hypothesis of canine domestic aggression postulates that the primary causes of aggression are related to social triggers that threaten (defensive) or challenge (offensive) the dog's ability to optimize survival security (comfort + safety) and well-being by (1) thwarting the dog's ability to escape to safety when threatened with danger, (2) interrupting the relief or relaxation phase of safety by invading the safe refuge, (3) intrusion or forcible theft of a valued comfort activity or object, (4) interruption of a survival activity conducive to comfort (e.g., eating or sleeping) (5) conditioned stimuli acquired in association with items 1 to 4 and the integration of ambivalent (nervous/insecure) social and place attachments, and (6) acquired triggers that activate autonomic preparatory arousal and sympathetic tensions conducive to the activation of the antipredator mode. Whether a dog adopts a defensive or offensive tactic depends on the incentive operating at the moment of arousal (fear or anger) and history of consequences resulting from past autoprotective actions (see *Species-typical Defensive and Offensive Aggression* in Chapter 7).

The ability to sneak off with food objects left unattended or discarded may have been an important source of nutrition in the dog's evolutionary past. With the loss of predatory modal behavior, dogs may have integrated scavenging and pilfering survival skills to enhance their ability to survive as they became increasingly dependent on human resources for survival. Dogs that succeeded in getting away with such pilfery probably enjoyed a higher likelihood of survival, but stealing food may have exacted a heavy penalty if the dog was caught in the act, perhaps exerting selection pressures that gradually encoded relevant sensory, cognitive, and emotional propensities improving the dog's ability to interpret and anticipate human deictic (pointing) signals and threats (e.g., finger and gaze directional commands) and attentional states (see *Deictic Signals and Directional Cues* in Chapter 10). These survival skills may have included defensive strategies to evade capture or to escape, if caught

(nip), perhaps learned in the context of certain play activities. Many of these enhanced adaptations and phylogenetic survival skills appear to be patched into canine play via augmented capacities for forming complex social attachments and coping with social ambiguity and uncertainty—critical paedomorphic changes that shadow decreasing predatory self-sufficiency and reduced fear of humans in the process of promoting a lifelong dependency on humans. These paedomorphic changes enhancing the dog's ability to form affectionate and playful relationships enable the dog to integrate the phylogenetic survival skills and coping abilities needed to adjust to domestic life.

Taking a forbidden item, evading capture, and then escaping to a safe refuge with the prize are part of a highly prepared sequential pattern that is rapidly learned by dogs. Mishandling of such exchanges may integrate problematic autoprotective dynamics, perhaps facilitating overt antipredator defenses in adulthood toward family members. For example, punishing a dog after forcing it out of a safe refuge, grabbing a leg or tail and dragging the dog into the open, chasing and cornering it with the help of other family members (particularly boisterous children), or prying objects out of the dog's mouth appear to be correlated with adult aggression problems. Similarly, punitive handling associated with safe havens, such as repeatedly grabbing a dog by its collar or scruff and pulling or throwing it off furniture, may promote increased vigilance and readiness to bite when approached under similar circumstances, especially in cases where reactive exchanges are a prominent part of a general pattern of daily conflictive interaction and ineffectual discipline. Most canine reactive behavior is the mirror reflection of incompetent human control efforts. The antipredatory mode appears to mobilize stress-sensitized flight-fight-freeze networks formed in association with inescapable interactive conflict. Reactive autoprotective behavior is distinguished by the presence of a preemptive negativity bias and automatic adjustments in response to ambiguous or ambivalent social stimuli. In contrast, proactive interaction and training activities integrate a positive preemptive social orientation and bias toward social uncertainty via structured exchanges conducive to an adaptive coping style. In addition to the mutual autonomic attunement and balance mediated by structured training, cynopraxic procedures serve to activate flirt-play, forbear-nip, and forgive-reconcile antistress and antiaggression systems (see *Phylogenesis, Polymorphism, and Coping Styles* in Chapter 6)—changes conducive to an enhanced capacity to cope with ambiguity, ambivalence, and novelty. Affection and playfulness are the reflection of preemptive emotional and behavioral biases that govern an adaptive coping style organized in association with the integration of secure social and place attachments and a trusting bond—changes incompatible with the dispersive tensions and dynamics that coalesce in the expression of impulsive or reactive autoprotective attacks.

The binding of attentional functions to chronic social ambivalence and entrapment dynamics diverts adaptive resources away from social engagement, cooperation, and reward-seeking activities. This shift of attentional focus is not only correlated with aggression but is hypothesized to represent a significant proximate factor mobilizing the autonomic misattunement and emotional distress conducive to ambivalent attachments, a reactive coping style, and the activation of an antipredatory mode of social interaction. The notion of an autoprotective phenotype activated in response to social conflict and entrapment appears to offer a far more useful way for studying the motivational and social etiology of aggression problems than does the social dominance narrative. According to cynopraxic theory, the interaction between friendly familiars consists of transactions that evoke feelings of comfort and safety and mutual autonomic attunement while promoting secure attachments. The refinement of social adjustments and changes conducive to mutual autonomic attunement and secure attachments is mediated by an adaptive coping style emerging in association with autoinitiated control incentives, prediction-control expectancies, and calibrated emotional establishing operations in the context of mutually

beneficial cooperative exchanges and fair-play compromise. In contrast, social interaction lacking sufficient consistency to promote an adaptive coping style and secure attachments promotes nervous attachments, dispersive tensions, and autoprotective behavior arising in association with social ambivalence (apprehension and resentment) in response to inescapable coercion, exploitation, and domination. Under the influence of coercion and inconsistency, social behavior becomes increasingly alloinitiated, dependent, and reactive. Dogs showing a reactive coping style may lack the ability to competently autoinitiate behavior based on proactive control incentives. In addition, such dogs appear to lack the requisite autonomic and emotional regulation needed to integrate and refine secure social and place attachments. According to cynopraxic training theory, the autonomy of interactive exchanges is a critical factor mediating adaptive social behavior and secure attachments. Social interaction lacking sufficient order (predictability and controllability) and variety to support autoinitiated behavior and an adaptive coping style will exert an intrinsically disorganizing influence on attachment behavior via social ambivalence, dispersive tensions, autonomic misattunement, and the integration of a reactive coping style. These observations emphasize that freedom and choice are critical aspects of social interaction conducive to the integration of an adaptive coping style and behavior incompatible with autoprotective behavior.

The motivated diversion of attentional and social resources away from the proactive processing of social exchanges appears to figure prominently in the etiology of reactive and impulsive social behavior and the activation of a antipredatory mode. Whereas attentional disengagement results in increased social anxiety and decreased selective attention and impulse control, social disengagement results in repulsion (irritability and intolerance) and withdrawal of the autonomic attunement that mediates attachment behavior. With the retraction of attentional and social engagement, family members may become increasingly alien and threatening (estrangement) to dogs. As a result of these autonomic, cognitive, and emotional changes, antipredator strategies become increasingly reactive, taking an active (flight-fight) or passive (freeze-helplessness) motivational direction, depending on the dog's temperament and the relative predominance of state versus trait anger and anxiety. The associated behavioral inhibition, withdrawal, and reactive irritability shown by such dogs may profoundly impair their ability to engage in competent social behavior. Such dogs may meet unwelcome approach and proximity with autoprotective conflict or attack. In other cases, perhaps where severe punishment has been used to suppress threat autoprotective threats, the dog may simply withdraw inwardly, becoming rigid and unresponsive to human contact. In contrast to nervous attachments, which reflect insufficient autonomic and emotional regulation to support impulse control and an adaptive coping style, insecure social attachments develop in association with an excessive and exclusive dependency on particular persons and places for autonomic and emotional regulation. Under the influence of social ambivalence and entrapment, insecure attachments may be focused on specific persons (e.g., adult parent) and places within the home (e.g., crate, sofa, or bed). Family members not included may be treated as threats insofar as their interference disturbs the comfort and safety obtained by the dog from being in close contact with the preferred attachment object or place. The loss of trust (disconfirmation of a safety expectancy) and the gradual or rapid withdrawal of attentional and social resources from an insecure attachment object may generate an increasing vulnerability for panicogenic arousal and explosive behavior in response to ambiguous interaction or handling perceived as threatening. For example, punitive efforts aimed at suppressing low-grade threats and growls shown by such dogs—displays that essentially signify inhibition and uneasiness about launching into an attack—may disrupt the dog's ability to process (inhibit and disinhibit) threat displays sequentially. In response to such mismanagement, the dog might learn to block low-grade threats by internalizing attentional resources and by coping passively until a flash point of

no return might be reached and an inappropriate attack is released under the exigency of blind panic.

In addition to the effects of social and attentional disengagement on a heightened risk of impulsivity, overly vigilant and apprehensive dogs may show cognitive deficiencies that impair their ability to shift attention selectively and to adjust emotional arousal in a phase-flexible way in response to ambiguous or novel social stimuli. Ambiguous signals may pose particularly onerous interpretive challenges for such dogs. Dog owners showing power-dominance conflicts and uncertainty about their ability to control social exchanges perceived as challenging their authority or showing signs of incipient household aggression may probe the dog with intentional and unintentional ambiguous signals to test its propensities, but in so doing only further agitate the dog and aggravate the problem. Low-grade reactive threats or growling prompted by ambiguous probes may cause the owner to punish the dog and thereby confirm the threat significance of ambiguous signals and increase the dog's reactivity and potential for releasing forceful autoprotective attacks toward similar social signals in the future. The repeated evocation and punishment of low-grade threats may systematically reduce the social trust (benefit of doubt) that normally inhibits reactive adjustments to ambiguous signals, causing the dog to become increasingly autoprotective and reactive when in doubt about the significance of social exchanges.

Ontogeny and Reactive Behavior

The process of autonomic attunement and behavioral integration appears to emerge early in life and is strongly influenced by a puppy's experiences prior to entering the home.

Antistress Neurobiology, Maternal Care, and Coping Style

Maternal care exerts several prominent effects on an offspring's ability to cope with social and environmental stressors in adulthood. These behavioral effects are reflected in numerous neurobiological changes that facilitate antistress capacities. For example, maternal responsiveness, nursing position, grooming, and licking behavior are closely tied to the density of oxytocin receptors expressed in brain areas mediating social and maternal behavior (e.g., the lateral septum and medial preoptic area). Rodent mothers providing high levels of grooming and licking also show significantly higher oxytocin-receptor densities in areas of the brain that mediate alarm and reactive behavior (e.g., the central nucleus of the amygdala and the bed nucleus of the stria terminalis) (Champagne et al., 2001). Most interestingly, however, is the finding that the mother's pattern of grooming and licking appears to stimulate the expression of a similar pattern of oxytocin-receptor densities in her daughters, thereby programming a maternal style resembling her own. In addition to being better mothers, the offspring of competent mothers are significantly less fearful of novelty than are offspring cared for by mothers that provide less grooming and licking care (Caldji et al., 1998). These less reactive offspring show increased gamma-aminobutyric acid/benzodiazepine (GABA/BZ)-receptor densities in the lateral, basolateral, and central nuclei of the amygdala. In addition, offspring receiving quality maternal care show decreased corticotropin-releasing factor (CRF)-receptor expression in the locus coeruleus together with increased α_2-adrenoceptor densities, changes consistent with reduced emotional reactivity.

Mothers may also transmit antistress effects to their young via lactation. Offspring of mothers given water tainted with corticosterone show a significant reduction in serotonin (5-hydroxytryptamine or 5-HT) subtype 1A receptors in the hippocampus (Meerlo et al., 2001). The offspring appeared to cope with stressors in a more passive manner than did controls, a change that reflected reduced reactivity rather than inhibition due to anxiety. Although chronic exposure to excessive corticosterone is harmful, moderate levels of the hormone ingested during lactation appear to produce beneficial effects on an offspring's ability to cope with stress in adult-

hood. Affected animals show improved learning abilities, reduced fearfulness, and a higher density of glucocorticoid receptors in the hippocampus—a change consistent with enhanced hypothalamic-pituitary-adrenal (HPA)-system regulation (Catalani et al., 2000). These various findings support the hypothesis that maternal care may *program* emotional and behavioral responses to environmental and psychological stressors that alter an offspring's coping style, perhaps by modifying thresholds controlling the activation of the flight-fight system.

The distribution of 5-HT and glucocorticoid receptors traced out during infancy appears to play a profound role in determining a dog's relative ability to cope with social stressors in adulthood. Postnatal handling has been shown to reduce significantly the density of 5-HT_2 receptors expressed in the frontal cortex and the hippocampus of adult animals, while 5-HT turnover and the density of glucocorticoid receptors in the amygdala and hypothalamus are left unaffected (Smythe et al., 1994). The reduced expression of frontal 5-HT_2 receptors may have relevance with regard to the etiology of impulsive aggression in dogs. Recent neuroimaging studies performed by Peremans and colleagues (2003) have found that dogs showing impulsive aggression exhibit increased 5-HT_{2A} receptor-binding potential localized in frontal cortical areas in comparison to nonaggressive dogs. They found no difference in the binding potential of 5-HT_{2A} receptors expressed in subcortical areas between aggressive and nonaggressive dogs (see *Stress, 5-HT_{2A} Receptor Upregulation, and Aggression* in Chapter 10). Also of interest are findings showing a close relationship between 5-HT and thyroid activity and infant stimulation. Meaney and colleagues (1987) showed that the distribution of 5-HT receptors fostered by neonatal handling depends on the activation of the pituitary-thyroid system and the release of triiodothyronine (T3). T3 stimulates the raphe bodies to release 5-HT into the ascending serotonergic system. 5-HT networks appear to guide the expression of cortical and hippocampal glucocorticoid receptors (Meaney et al., 2000). The early functional relationship between thyroid and 5-HT in organizing the stress-management system underscores the important role that 5-HT plays in mediating allostasis. The close linkage between 5-HT and thyroid in the organization of stress circuits gives some credence to the combined use of serotonergic antidepressants with low-dose thyroid in the treatment of certain aggression problems (see *Stress, Thyroid Deficiency, Hypocortisolism, and Aggression*).

Parent-Offspring Conflict and Interactive Conflict

Trivers (1972) proposed that an inherent conflict between parents and offspring revolves around the giving and receiving of care and nurturance. The theory postulates that mothers are selected to provide enough care to ensure the survival of their young but without impairing their ability to reproduce and care for more offspring in the future, striking a balance referred to as *parental investment* (PI). In contrast, the offspring appear to be governed by an exploitative incentive to inveigle the mother into giving more care than she can provide without endangering her ability to produce and care for more young. The parent-offspring conflict is hypothesized to exert a potent and dynamic influence on the development of social behavior, prompting a variety of psychological and behavioral strategies for manipulating the mother into giving more care than her PI allows:

> How is the offspring to compete effectively with its parent? An offspring cannot fling its mother to the ground at will and nurse. Throughout the period of parental investment the offspring competes at a disadvantage. The offspring is smaller and less experienced than its parent, and its parent controls the resources at issue. Given this competitive disadvantage the offspring is expected to employ psychological rather than physical tactics … It should attempt to induce more investment than the parent wishes to give. (Trivers, 1974:257)

The striving to induce the mother to give more care then her PI permits may be organized into analogous efforts to obtain from nature and others more than they are willing or able to give, as well. In fact, the dynamic

related to the parent-offspring conflict may be embedded in many motivational processes driving the optimization of control over significant social and environmental events and resources. According to this hypothesis, the core active incentives—exploitation and power—governing purposive behavior are balanced and tempered by submissive ritualization that may originate in the appeasement and begging strategies shown toward the mother to squeeze more attention and care from her. These core incentives may be further tamed in the context of play with siblings and the acquisition of social codes based on fair play. Perhaps, even what the dog values as a reward and abhors as punishment can be traced to the mother's contingent provisioning or withholding of nurturance (e.g., social proximity, tactile stimulation, and appetitive gratification).

The manner in which the mother copes with the conflict and manages the manipulative efforts of her offspring to exploit her may exert a lasting effect on the way the puppy copes with limits and social conflict situations in adulthood. The hypothesis being posited here is that the conflictive dynamics between the puppy and mother may contribute to the mobilization of either an adaptive or a reactive coping style, depending on how the mother responds to the puppy's care-seeking behavior. Accordingly, strategies developed to cope with the threat of maternal punishment and the delay or denial of anticipated care (frustration) may anticipate the organization of passive modal strategies (e.g., hesitating and delaying). In addition, the dynamic balance of activity success and failure associated with parent-offspring conflict may play a prominent role in regulation of autonomic tone mediating the organization of secure, nervous, and insecure social and place attachments. The relative balance of success versus failure in a puppy's efforts to attain comfort and safety or to exploit the mother might impact significantly on how well the puppy copes with anxiety and frustration associated with interactive conflict within the home, potentially exerting a profound influence on the organization of impulsive and reactive behavior. Mothers that are excessively responsive or unresponsive, punitive, or unpredictable in response to their offspring's care-seeking behavior may produce lasting developmental changes in canine personality development and capacity to integrate an adaptive coping style and concept of fairness. The good mother sets limits and manages conflict with her young in a constructive way, fostering a flirt-and-forbear/forgive (reconcile) orientation toward social conflict. Cognitive and emotional processing associated with parent-offspring conflict may contribute significantly to social engagement and shape tendencies toward a fair, exploitative, despotic, or an avoidant orientation toward others. Ideally, the transition from nursing and an exploitative dependency on the mother to a relationship based on affectionate submission, respect for limit, and ability to compromise sets the stage for the integration of harmonious relations in the home.

Maternal Mistreatment

Canine mothers exhibit significant variability in the way they cope with puppy care-seeking excesses. How the mother responds to demands for care depends on a huge array of variables, including allostatic load, available nutrition, the size of the litter, maternal experience, quality of maternal instincts, individual differences expressed in the behavior of the offspring, and the way the mother was cared for by her own mother. In addition to regurgitating for the puppies and providing them with solid food, the mother may cope with offspring care seeking by evading or shortening nursing or by leaving her young alone for longer periods. The mother may also assume ownership of the activity and set limits on it by means of a variety of overt tactics, including punishment. Highly competent canine mothers appear to make a deliberate effort to calm tensions and reduce conflict by means of gentle and slow movements. Rather than punishing her young, such mothers may block, nudge, or delicately muzzle her offspring to discourage unwelcome nursing while encouraging compromise. The mother appears to persuade her young to comply with a mild and affectionate approach rather

than resorting to intimidation and coercion, but the most patient and competent mother is not above applying a sharp rebuke against an overly obtrusive offspring.

In contrast to the competent maternal behavior just described, Rheingold (1963) found that canine mothers showed a wide spectrum of species-typical agonistic behavior toward their offspring (e.g., growling; barking; baring teeth; inhibited biting around the head, neck, or muzzle; brief shaking; or using a paw to hold the puppy down or pouncing at it) to which the puppies reciprocated various passive-submission displays (e.g., yelping, backing, lowering and submitting, rolling over, or scampering away). Of the five mothers and litters studied, two mothers habitually punished their offspring: a brown sheltie and a cocker spaniel. These mothers were observed continuously from shortly after birth of the litters to week 9. From the period immediately preceding the onset of weaning and extending to week 9, maternal agonism was frequent and severe in these mothers. A beagle and a black sheltie were never observed to punish their offspring, perhaps only because observations of those dogs were stopped at days 29 and 19, respectively. A merle sheltie was observed to begin punishing her puppies shortly before being removed from the study at day 42, a time coinciding with the peak of punishing activities exhibited by the brown sheltie and the cocker. The brown sheltie was often found in the whelping box from which vantage she would threaten her puppies if they attempted to enter. The cocker made normal life impossible for her offspring, attacking them whenever they attempted to eat from wet mash pans, when they approached her, or even when facing in her direction while she ate. Both the brown sheltie and cocker spaniel were observed to punish their puppies several times during most of the 15-minute observation periods. In addition to being frequent and severe, the punishment was delivered on an inconsistent basis, perhaps inoculating their offspring with an emotionally reactive orientation to social limitations, a tendency toward forming nervous or insecure attachments, and a reactive autonomic tone and HPA-system response to stress. Despite the harsh treatment received by the puppies, they continued to approach their intolerant mothers throughout the duration of the study:

> The pups persisted in trying to nurse, to make contact and to play with the mother. A cocker pup might flee from the mother's punishment, yelping and dragging its rear as though in pain, then, shortly, return to the activity. On the last day of observation [day 66], pups were still being punished upon approaching the mother, but they no longer tried to suckle.
>
> The pups' persistence should be weighed against the inconsistency of punishment, for the same act would be followed with punishment one moment but not the next. At times mothers seemed distracted by outside noises; at times they dozed. Then, especially, the brown Sheltie pups would try to enter the whelping box from the side or in back of the mother. Sometimes individual pups were indulged; the brown Sheltie, for example, occasionally permitted the runt of the litter to sleep in the box with her while the other pups were kept outside. (Rheingold, 1963:188)

Adverse stressors and insults taking place during exposure to an inconsistent, intolerant, and inimical mother, as in the case of these mothers, would likely install autonomic changes conducive to a coping style similar to her own and inoculate them with a tendency to form nervous or insecure attachments. Relevantly, Rheingold described the play behavior of these puppies as a "low frequency" activity. Play appears to serve a significant role in integrating secure social and place attachments and promoting autonomic balance (calm). Calcagnetti and Schechter (1992) found that rats given access to a play partner while in a place that they previously avoided showed a significant conditioned place preference toward that area as a result of playing there, spending nearly 200% more time in the area than before. Wilsson (1984) reported that puppies exposed to excessive inhibited biting in association with weaning were less willing to approach a passive handler. Also, the amount of growling received by the puppy was significantly correlated with a reduced willingness to fetch a ball, perhaps stemming from autonomic changes reducing

its ability to play. After the aggressive mother was taken away at week 8, her offspring were described as "noisy and violent" (112), consistent with the possibility that conflictive interaction may have installed a reactive autonomic tone. The coincidence of weaning with dramatic autonomic shifts, as indexed by heart-rate changes (see *Play and Autonomic Attunement*), suggests that during this period the puppy may be especially vulnerable to integrate autonomic disturbances via maternal mistreatment, perhaps damaging the offspring's ability to form secure attachments and predisposing it to express a reactive coping style. The quality and quantity of play during this period may represent a useful marker or indicator of risk for reactive problems, since competent coping in response to agonistic challenges appears to depend on the autonomic attunement that play appears to provide (Van den Berg et al., 1999) (see *Play, Social Engagement, and Fair Play*).

Audience effects and observational learning might further contribute harm by inculcating social schemata consistent with an aggressive or avoidant social orientation (see *Maternal Influences on Secondary Socialization* in Volume 1, Chapter 2). According to this hypothesis, the mother's behavior toward sibling rivals in association with conflicts over significant objects, resources, or locations may rapidly organize schemata and behavioral scripts matched to the scenes enacted between the mother and rivals. During demonstrations, bystanders observing the interaction might be assumed to acquire social information derived from watching, listening, and processing the proxemic exchanges between the mother and rival siblings. These demonstrations between the mother and sibling rivals should be of considerable interest to bystanders. Combining the direct emotional experience of previous maternal punishment (conditioned arousal component), coupled with observations of siblings receiving maternal punishment, a variety of complex emotional and behavioral propensities may be schematically etched into the puppy's memory and organized into prepared behaviors ready for rapid acquisition later on in life. In adulthood, these prepared behaviors and propensities may be enacted in response to situations resonating with emotional memories integrated in association with maternal punishment (see *Model/Rival Theory, Fair Play, and Sibling Hierarchy*).

Natal Environment and Autonomic Attunement

Subtle changes to rearing conditions may produce pronounced short-term and long-term modifications in a dog's capacity to cope with stress. For example, Wilsson and Sundgren (1998) found that changing the flooring material of the whelping box from cardboard to a soft piled blanket exerted a lasting effect on both puppy and adult temperament test scores, pointing to the important role of quality-of-life influences for mobilizing pronounced changes in behavior. The mere presence of a soft comfort object appears to contribute a positive regulatory influence on the development of autonomic tone. Puppies given a soft stuffed animal through week 4 showed less distress when they were left alone in a strange place with the comfort object than did puppies not provided such preexposure to the object (Marr, 1960). Marr (1964) also demonstrated that tactile, kinesthetic, and visual stimulation early in life alters the way puppies cope with emotionally provocative situations. As the result of being repeatedly petted, rocked back and forth, or exposed to a flashing light while facing a circular shape, 3-week-old puppies subsequently spent more time in close proximity with the shape and showed less emotional distress when tested alone with the shape at week 4 in comparison to nonstimulated controls. The stimulated puppies appear to have connected the circular shape with autonomic regulation incompatible with reactive emotional arousal. Marr's finding emphasizes the lasting subtle effects of early stimulation on the integration of sympathovagal tone with place attachments.

Appleby and colleagues (2002) have suggested an apparent linkage between natal environmental conditions and adult aggression and avoidance behavior in dogs. Questionnaire data provided by dog owners appear

to indicate that puppies obtained from nondomestic sources (e.g., commercial kennel) may be more prone to exhibit certain forms of aggression and avoidance behavior than are puppies obtained from a home environment (e.g., backyard breeder). Dogs acquired from nondomestic sources appear to be at an increased risk of showing aggression toward unfamiliar persons, especially while at home. These dogs also showed more aggression while receiving veterinary examinations. A possible explanation for such a linkage may be an increased sensitivity among puppies reared under nondomestic conditions to aversive stimulation and restraint by a strange person in an unfamiliar place. No relationship was extracted between the type of natal environment and intrafamilial aggression, suggesting that the combination of social and environmental familiarity may reduce the risk of reactive behavior associated with adverse developmental influences, whereas a lack of social familiarity or nervous attachments may increase the risk of such behavior. Puppies obtained from nondomestic sources at week 8 or later showed significantly more fear-related behavior than did puppies obtained prior to week 8.

These findings are consistent with the notion that vulnerability for reactive behavior is organized early in life (before week 8), and that subsequent experiences may augment or diminish reactive tendencies. First impressions are lasting, especially so for puppies between weeks 8 and 10 (see *Learning and Trainability* in Volume 1, Chapter 3), a time when many young dogs are taken to the veterinary hospital for the first time. Early aversive or frightening experiences may establish lasting anxiety-evoking associations with the hospital environment. Stanford (1981) found that 60% of dogs entering a veterinary hospital showed signs of fear and urinated. When restrained, many of dogs (18%) were classified as "fear-biting." These dogs showed reactive vocalization, efforts to escape, and aggression; 17% of the dogs were described as showing a willing entrance and controllable demeanor, but still urinated. Remarkably, only 5% of the dogs were observed to enter willingly and did not urinate (N = 462). These findings, combined with those of Appleby and colleagues, recommend that efforts be made to minimize young puppies' exposure to discomfort or frightening restraint (e.g., wobbly or noisy exam tables and scales) during veterinary visits, especially during the first few appointments. Puppies that show reactive tendencies during routine examinations should prompt appropriate counseling and referral to a cynopraxic therapist or trainer for supportive behavioral care.

Household Stress and Aggression

The adoption transition is often highly stressful for young puppies (see *Adoption and Stress* in Chapter 4)—stress that may be magnified by mishandling, manhandling, and excessive or inappropriate isolation and confinement (see *Dangers of Excessive Crate Confinement* in Chapter 2). Gantt (1944) observed that when dogs were moved from a farm or home environment to the increased confinement and reduced quality of life associated with the laboratory, they often underwent dramatic and persistent behavioral and emotional changes in the opposite directions of depression or hyperactivity, depending on their temperament and the balance of excitatory and inhibitory tendencies expressed. Excessive confinement within the home environment may increase behavioral reactivity in predisposed puppies. Although the effects of crate training and lengthy crate confinement and isolation on puppies within the home environment have not been studied, the preponderance of experimental evidence seems to suggest that stressful restraint, confinement, and isolation exert a problematic influence on a young animal's ability to cope with stress. Rats, for example, exposed for 21 days to 6 hours of daily restraint in a narrow wire-mesh tube in their home environment show significant changes in stress-related aggressive behavior toward cagemates (Wood et al., 2003). The experimenters found that the initial exposure to restraint had a sharply inhibitory effect on aggressive behavior toward cagemates; however, a trend toward increasing irritability and aggression became evident over

the next several days and significant by day 14. Aggressiveness continued to increase through day 21. Over this same period, the unrestrained controls showed less aggressive behavior toward cagemates. Excessive confinement and isolation may increase allostatic load while decreasing a dog's ability to cope with stress constructively, impair its ability to cope with novelty and uncertainty, impede its ability to form secure attachments with family members and the home, and promote reactive behavior. Aside from the potential emotional harm and welfare concerns associated with excessive crate confinement and isolation, dogs that are confined in zinc-galvanized wire crates may ingest potentially toxic levels of zinc by chewing or licking the crate (Goicoa et al., 2002). Both the zinc coating as well as "white rust" are apparently toxic (Howard, 1992). Dogs exhibiting serious impulsive aggression have been found to show significantly higher concentrations of plasma zinc (1.69 ± 0.49 μg/ml) in comparison to nonaggressive dogs (0.76 ± 0.16 μg/ml) (Juhr et al., 2003).

There is a natural attraction that inclines dogs to follow human leaders, to engage in give-and-take exchanges, and to participate in cooperative projects. Such relationships are associated with emergent affection, trust, playfulness, and the integration of secure social attachments. Under the influences of leadership and nurturance, the dog copes with human control efforts by integrating a voluntary subordination strategy (VSS) and cooperative relations with the human leader; whereas, in situations in which subordination is displaced by subjugation and coercion, the dog may cope by mobilizing an involuntary subordination strategy (ISS), giving rise to significant interactive conflict and adversarial fallout (e.g., anxiety, irritability, intolerance, and resentment) (see *Involuntary Subordination and Canine Domestic Aggression* in Chapter 7). Secure attachments and an adaptive coping style are necessary for dogs to construct a belief or *illusion* that the world is safe, orderly, and responsive to autoinitiated control efforts. Conflictive attachment dynamics, perhaps originating in the mother-offspring relationship and perpetuated by domestic social ambivalence and entrapment, may promote ambivalent (insecure/nervous) social and place attachments, incompetence, and a reactive coping style. These influences may diminish or eclipse the developing dog's ability to form a bias of safety to buffer nerves when exposed to sudden change or social novelty and to provide the confidence needed to organize competent social behavior under such adverse circumstances. Just as the mother's licking, nibbling, nudging, and affectionate attention toward her offspring appear to mediate an autonomic capacity to form secure social and place attachments in adulthood, supportive family interactions with the puppy may provide a protective influence against adverse developmental stressors, while helping to mobilize an affectionate and playful orientation toward social novelty, ambiguity, and unexpected change that is incompatible with reactive behavior.

Living Space, Proxemic Relations, Inattentiveness, and Autoprotectiveness

Just as the ideal canine mother exhibits a high degree of forbearance and consistency in the management of her offspring and their appetites, the human parent should set limits in the context of reward-based leadership and training. By emulating the mother's use of the least force and threat necessary to discourage obtrusive behavior, the cynopraxic trainer works to deflect and redirect competitive tensions into alternative outlets and avoids placing undue emphasis on punishment. Play and safe exposure to varied social and environmental stimuli at a young age are critical aspects of training dogs to respond confidently to unfamiliarity and uncertainty in adulthood. During interactive exposure, habituation and latent learning processes are constantly at work shaping competent sensorimotor gating and orienting functions. Habituation and latent learning provide a foundation for the organization of an adaptive coping style. Preventive-exposure training (PET) (see *Habituation, Sensitization, and Preventive-exposure Training* in Chapter 3) serves to transform the home and neighbor-

hood into places perceived as safe and coherent while concurrent integrated compliance training (ICT) helps to transform sources of interactive conflict into opportunities for reward and play.

Interactive conflict typically develops around activities that are intrinsically gratifying to the dog but that are incompatible with domestic control interests. Social and environmental conditions perceived as punishing (unrewarding) or unsafe, coupled with interactive conflict, stress (i.e., state anxiety and anger), and inescapability, may serve to transform the security of the home into a place of anxiety, anger, and entrapment. The resulting interactive conflict and stress may trigger various reactive and coercive strategies by the owner to prevent or suppress the unwanted behavior. Most of these efforts are aimed at depriving the dog of freedom or forbidding it access to the house. Depriving the dog of freedom of movement and access to the home and interaction with family members by excessive restraint or abusive training practices may temporarily empower the frustrated owner with an illusion of mastery but may actually do significant harm to the bond and degrade the dog's quality of life, as well as set the stage for more serious adjustment problems. Instead of learning how to predict and control significant events competently while learning to adapt and cope, the socially antagonized and entrapped dog may withdraw, become marginalized, and establish trigger *safe* areas within the home reserved for itself and preferred others, but that are defended aggressively against the intrusion of unwelcome others.

According to the foregoing hypothesis, many forms of intrafamilial aggression may be better understood and treated as originating from proxemic autoprotective incentives rather then hierarchical challenges or threats to the dog's perception of rank. Such aggressive episodes frequently occur without apparent provocation while the dog is resting in a favorite place or while in a location associated with or containing a prized object. Some of these dogs may also show strong threat behavior toward certain family members when the dogs are approached while inside a crate. The victim's mere presence or intrusion into a certain location may disturb the dog's mood and trigger impulsive autoprotective adjustments. According to a proxemic analysis, such attacks may be provoked by the victim's unwelcome intrusion into an intimate zone of comfort and safety in the absence of appropriate social affiliation or attraction. In some cases, dogs may threaten or attack in response to violations of social codes associated with interference while sleeping or resting or when in possession of objects (e.g., rights of first possession). In other cases, the dog's attachment to the place may be stronger than its attachment to the family member; in other cases, the family member may actively *repulse* the dog. While ensconced in such trigger areas, such dogs may permit access to certain family members with whom they appear to be strongly attached, while threatening or attacking other family members with little warning if they engage in intimate proxemic behaviors (e.g., pet, hug, cuddle, or pick up). The occurrence of aggression around locations providing the dog with emotional regulation conducive to comfort and safety (insecure place attachments), together with a state of reduced attention and unwelcome proxemic interactions, set the stage for a rapid vagal shift from inhibitory to excitatory arousal. However, instead of shifting back to a parasympathetic mode of relaxation, the impulsive aggressor may rapidly escalate into a catastrophic surge of sympathetic arousal and the phasic disinhibition of aggressive impulse. These observations suggest that impulsive aggression of this type may stem from regulatory attention and impulse-control disturbances affecting vagal tone. In general, dogs fitting this description rarely go out of their way to bite and typically bite only when approached or disturbed while in specific places associated with comfort and safety.

Although a subgroup of these dogs appears to be selective with respect to preferred targets and tends to focus attacks on family members, the notion that such dogs attack only household members is dubious, since many of these dogs will also attack nonfamilial visitors who violate defended trigger areas. Gershman and colleagues (1994) found that dogs with a

history of nipping or biting directed against family members were just as likely to attack nonfamily members. The tolerance that visitors and persons away from home appear to obtain, at least temporarily, is hypothesized to stem from the increased attention and interest that social novelty evokes in such dogs. Focused attention and social exploratory behavior is hypothesized to increase vagal tone, making catastrophic or explosive shifts of sympathetic arousal less likely to occur toward unfamiliar persons. The attentional disengagement and tuning out that impair impulse control and reduce sympathovagal tone appear to develop in association with three patterns of social interaction. Under the constraints of entrapment, dogs may cope with inescapable social anxiety and ambivalence produced by particular family members by actively ignoring them, a phenomenon referred to as *defensive inattentiveness*. The dog may also withdraw attention from family members that pay it little or no attention, a process of disengagement referred to as *reactive inattentiveness*. Defensive and reactive inattentiveness are closely associated with the withdrawal of social engagement, depersonalization, and the establishment of rigid social relations and roles.

Attentional and impulse-control processes are also adversely affected by social interaction that lacks consistency and relevance, causing the dog to actively disengage attentional resources from family members whose communicative behavior is irrelevant to the occurrence or nonoccurrence of significant events. Dogs also appear to withdraw attention and tune out from persons lacking competent leadership qualities. Family members who seek to establish control over the dog but who are unsure of their ability and proceed haphazardly or coercively (incompetently) may project ambiguity and mixed messages that are difficult for the dog to sort out and match with appropriate emotional establishing operations and response selections. Such ambiguity in the communication style of insecure leaders plays a prominent role in the development of social ambivalence and may help to explain the dog's aggressive response to seemingly benign signals. Proxemic signals given by an insecure or insincere leader may communicate a negative message despite a facade of friendly intent, perhaps expressing the powerless family member's underlying disappointment and resentment at failing to integrate secure affiliative power relations with the dog. The disengagement of attention resources from family members may impair socialization or reverse the effects of socialization, causing the dog to view family members as being increasingly unfamiliar via a process of depersonalization. According to cynopraxic theory, attention and impulse control are interdependent constructs that are closely integrated and attuned with autonomic processing. Orienting, attending, exploring, and playing activities serve to mediate enhanced familiarity, augmented sympathovagal regulation, and impulse control. In contrast, attentional disengagement and social avoidance result in decreased sympathovagal regulation, increased emotional reactivity, and lowered flight-fight thresholds. As the result of attentional disengagement, the approach of family members may trigger conditioned sympathoexcitatory shifts in autonomic arousal associated with interference and interactive conflict that have resulted in loss and risk in the past. The dog's efforts to ignore or tune out the person may serve only to relinquish impulse control and impair vagal control, perhaps via the activation of GABAergic neurons by arginine vasopressin (AVP) circuits at the level of the brainstem (Wang et al., 2002), resulting in the reduction of parasympathetic tone and generating a permissive state conducive to rapid sympathetic arousal and catastrophic autoprotective responses. Social ambivalence and entrapment dynamics may cause such dogs to defend the trigger area as an escape-to-safety refuge and default point of no return.

Social Spaces, Frames, and Zones

The living space or home range refers to the places routinely occupied or used by the dog and shared with others in the pursuit of everyday interests and reward. The living space of the home and surroundings consists

of local and global frames, spaces, and zones defined by individual attraction-repulsion dynamics and proxemic relations extending from the intimate safe center and moving outward to the unfamiliar and uncertain edge. Within the context of the home range itself, artificial global (e.g., walls and fences) and local (e.g. windows, doors, gates, and crates) frames define the spatial and physical contexts that set the stage for scripted social *scenes* or avoiding them (e.g., hiding behavior). The living space is framed into several social spaces distinguished by functional significance with respect to the sort of proxemic exchanges that the dog enjoys, tolerates, or might forbid depending on attraction, familiarity, and trust. Doors and walls artificially frame the home, thereby setting off intimate and safe spaces exclusive for use by family members to hide, rest, and obtain comfort (familial space), whereas fences globally frame the property and define an open and familiar space used to explore, play, and meet others (familiar space). The leash may be conceived of as framing a free-floating *intimate zone* between the handler and the dog and extending into the surroundings, representing variable degrees of familiarity and safety (transitional space). A satellite space containing the free-floating intimate zone is established wherever the handler and dog interact with each other. Finally, a training space is formed as the result of establishing a default hierarchy and leader-follower bond in association with limits set on pulling into the leash, jumping up, and biting on hands and clothing.

Most family dogs appear to treat visitors either as absentee pack members (insiders) deserving affectionate recognition or as intruding strangers (outsiders) warranting alarm and suspicion. Dogs that treat guests as part of an extended family-pack are typically highly demonstrative, exhibiting a high degree of social excitement and eagerness to make contact with people and other dogs; such dogs show minimal differentiation with respect to social space definition and represent a low risk of intrafamilial or extrafamilial aggression. On the other hand, dogs viewing visitors as outsiders often continue to exhibit a significant amount of wariness and aggressive readiness even after becoming thoroughly familiar with a visitor. Such a dog may accept and reciprocate friendly contact with familiar outsiders while in the yard but become reactive if they attempt to enter the house (violation of the familial space), especially if they are unattended by a family member. Also, such a dog may tolerate the approach of unfamiliar outsiders when away from home with a family member, but become strongly aroused if an unfamiliar outsider enters the yard unannounced (violation of the familiar space). Dogs combining a reactive vigilance for social novelty and sudden change (stimulation-seeking deficit), a propensity to discriminate aggressively between outsiders and insiders irrespective of familiarity, and a relatively low-fight threshold (trait anger) appear to be most prone to express a rigid watchdog script and extrafamilial aggression (see *Flexible versus Rigid Watchdog Scripts*).

Novelty, Sudden Change, and Reactive Adjustments

Escape to Safety versus Escape from Danger

Under natural conditions, the activation of phylogenetic survival modes mobilize drives that educe (not elicit) adaptive behavior, causing animals to strive against adversity and to take risks likely to improve their ability to survive and reproduce. For many animals, the neophobic stress evoked by unfamiliar stimuli and situations is overcome by forming a base of familiar and secure place and social attachments from where they can venture into unfamiliar surroundings by means of furtive sallies or more adventuresome journeys, depending on their ability to cope with uncertainty and risk. Knowing that they can scurry back into a hole or climb up a tree or fly away appears to increase the confidence of many animals to approach and explore promising novel objects. In any case, most animals appear to treat the exploration of novel objects and unfamiliar places as a source of risk and only take such risks to obtain a biologically significant advantage or reward. In nature, however, danger is at every turn and one cannot escape from its ubiquity; there are two primary solu-

tions: (1) escape to the security of the familiar and safe place or (2) confront the threat. Under threatening conditions perceived as inescapable with no hope of reaching safety, autoprotective panic or tonic immobility (behavioral helplessness) may ensue. Both of these reactive strategies to inescapable stressors are biologically organized to mediate adjustments to catastrophic situations where an escape to safety is blocked, leaving the animal vulnerable to extreme danger.

When startled and caused to flee, animals *escape to safety*; they do not merely *escape from danger*. This distinction is vital for understanding avoidance learning and how dogs learn to cope with novelty and danger. The fleeing animal is not stressed by the novel or fear-evoking stimulus per se but becomes distressed only if its ability to detect the threat is obstructed (i.e., reduced predictability) or its escape to safety is impeded or blocked (i.e., reduced controllability). If an animal can successfully dodge danger and escape to a secure and familiar place, it may slowly recover and return to the spot it had fled, taking significant predatory risks for the sake of increased food intake (Arenz and Leger, 1999). The validity of this notion of trade-off and flight to safety can be observed in the persistent escape and approach behavior of squirrels exploiting a birdfeeder; despite being repeatedly chased away by a dog and only narrowly escaping its teeth, a persistent squirrel does not appear to be rapidly deterred by the danger from returning to the feeder, nor does it show much evidence of fear while there. In fact, with every successful escape, the squirrel's confidence appears to grow, causing it to linger longer at the feeder before dashing off. The squirrel may even increase the frequency of its visits to the feeder, perhaps under the synergistic effects of appetitive reward and the reward of successful escape/avoidance. However, if the accustomed escape route is changed or blocked, forcing it to delay or take a detour, the squirrel will show a significant change in behavior as the result of the hindrance slowing its escape to safety. Subsequent to such events, the squirrel appears to take more time before returning to the feeder (if returning at all), becomes more vigilant while at the feeder (stopping to look and listen more often), and wastes no time in getting away from the feeder as soon as it detects the dog heading its way. Young squirrels appear to show far less vigilance than adult squirrels, evident from birdfeeder observations and also in the sluggish way in which they respond to other threats (e.g., cars). Arenz and Leger (2000) found that vigilance levels appear to be closely related to appetitive motivation and physical state, with squirrels fed a high-energy food (HEF) showing more vigilance than those fed a low-energy food (LEF). As the HEF squirrels matured, they showed greater body mass and were more vigilant than the LEF squirrels, suggesting that the malnourished and smaller LEFs were willing to take greater risks by reducing antipredator vigilance for the sake of increased food intake. Since vigilance is incompatible with eating, as the squirrel becomes increasingly vigilant and uncertain of its ability to escape the feeder location successfully, the tradeoff ought to become less attractive, with the squirrel gradually showing an escape-from-danger strategy and avoidance of the birdfeeder rather than an escape-to-safety strategy and approach to the birdfeeder.

The escape and avoidance behavior of squirrels appears to agree with experimental findings showing that safety functions as a reward in the acquisition of avoidance learning (see *Safety Signal Hypothesis* in Volume 1, Chapter 8). The acquisition of avoidance behavior varies proportionately to the relative length of time that an animal is exposed to danger and safety (Cándido et al., 2002). Under conditions in which the danger period is held constant, avoidance learning is slower when successful responses are followed by brief safety and more rapid when avoidance responses are followed by a longer period of safety (Cándido et al., 1989). If avoidance was acquired primarily as the result of escape from danger, then the relative duration spent in safety should be of little importance to the speed of acquisition, since the primary reinforcing event occurs at the moment of escape. As such, the safe situation need only confirm that a successful escape or avoidance response had occurred—information that should be of

greatest value at the moment the animal enters the safety box. An additional experiment varied the length of the danger period while keeping the length of the safety period constant. The results indicated that the acquisition of avoidance was accelerated if exposure to a dangerous situation was brief before the warning signal and shock were delivered, whereas acquisition slowed down if the time spent in danger was increased, causing a delay in the warning and shock. If escape from danger was the primary incentive underlying such avoidance learning, one would expect an opposite relation to prevail; that is, the longer the animal remained in danger, its motivation to escape should increase and thereby accelerate avoidance learning.

The pattern of avoidance learning just described is consistent with the notion that danger may function as a discriminative stimulus for an escape-to-safety response, whereas exposure to a lengthier period in the danger box may facilitate habituation and reduce the associative linkage between the box context and the postponed aversive event; that is, the danger box gradually becomes a safe box. The foregoing findings are consistent with an opposite extrapolation concerning the extinction of avoidance learning; namely, brief exposure to preevent danger followed by brief exposure to safety may exert a stronger influence on the disconfirmation of avoidance learning and the integration of abolishing operations than do lengthier periods of preevent danger followed by long periods of safety. According to this hypothesis, massed trials (brief danger > no aversive event > brief safety) should be transiently more effective than spaced trials (lengthy danger > no aversive event > lengthy safety) for mediating extinction, whereas, brief exposure to danger in anticipation of the aversive event followed by lengthy exposure to safety should produce the strongest avoidance learning. Consequently, repeated and massed exposure trials should work better to extinguish active-avoidance behavior, at least initially, whereas longer exposures to the danger situation followed by lengthy periods of subsequent safety appear to help habituate aversive contextual associations while consolidating incompatible expectancies predicting safety from the aversive event. Recent experimental work by Cain and colleagues (2003) supports the hypothesis that massed trials of extinction followed by spaced trials of consolidation training represent a more effective strategy for reducing fearful associations and avoidance than the converse strategy, but also see Martasian and Smith (1993) for variations affecting lengthy exposure versus distributed trials of response prevention.

Coping with Novelty and the Escape-to-Safety Hypothesis

The way in which mice cope with novelty also appears to support the escape-to-safety hypothesis. Mice are often described as being neophobic, but Misslin and Cigrang (1986) have reported that anxiety or fearfulness in response to novelty depends on how the novel object is presented. In comparison to mice that are physically placed into a novel situation and prevented from escaping to a familiar place, mice that are allowed to regulate how and when they approach and explore a novel situation from the vantage of a familiar place show little evidence of autonomic distress. Similarly, piglets cope with novelty by scampering as a group between familiar and unfamiliar areas, suggesting that the behavior may be a form of group play organized to enable the animals to explore novel areas and objects (Wood-Gush and Vestergaard, 1991). MacDonald (1987) found that wolf pups show significant individual differences in the way they enter into and explore an unfamiliar place. Among the pups studied, one showed a high level of confidence and willingness to enter an unfamiliar arena and explore novel objects (novelty seeking), while the others showed variable amounts of hesitation or reluctance (harm avoidance). The confident or leader pup appeared to facilitate other less confident pups to follow and approach novel objects, while fearful pups remained inside the start area. The way piglets and wolf pups explore and cope with novelty may reflect species-typical differences in the organization and function of their respective social hierarchies and the strategies that they use to hunt

and exploit environmental resources (Brown, 1966). For example, among field mice living in a natural habitat, social rank is closely correlated with differences affecting home-range exploratory behavior. Dominant mice range farther and explore the home range with greater confidence than subordinate mice. Subordinate mice were observed to stay out of the way of dominant mice and suspend object explorations if the dominant mouse was nearby. Among puppies, inappropriate punishment associated with house training may significantly alter their exploratory behavior and ability to cope with novel situations. In comparison to puppies trained with petting and food, puppies trained by blowing a puff of air into their ear or by rapping them with a rubber hose showed longer latencies to enter an unfamiliar area and explored by covering shorter distances at a time, suggesting increased tentativeness and anxiety (Matysiak et al., 1973).

In MacDonald's study, the leader pup was found to be the most successful of the group in its ability to control the bone in free-for-all dominance tests. The leader pup also exhibited the greatest confidence in response to the approach of a threatening familiar person opening and closing an umbrella. Pups that showed the greatest fearfulness toward the unfamiliar situation, refusing to enter the arena on their own or with the leader pup, exhibited the least fear toward a human stranger, whereas the leader pup showed the greatest fear toward the stranger. These findings suggest that there exist complicated relationships between social attraction and fear, nonsocial novelty seeking and harm avoidance, and dominance. In particular, an inverse relationship appears to exits between a fear of unfamiliar settings and things and a fear of unfamiliar persons. The relationship between social dominance and leadership in coping with unfamiliar situations and novel objects underscores the importance of leadership for facilitating exploration and learning. The follower/submissive traits mediating social subordination appear to be relatively independent, with the following being related to a fear of novelty and high social attraction and relative fearlessness, whereas submission is related to an inability to compete successfully over prized objects, perhaps as the result of being handicapped by a fear of unfamiliar circumstances. Wright (1980) reported a similar independence between competitive success and social dominance among German shepherd puppies. Like wolf pups, competitive success in the bone test is strongly associated with novelty seeking, but successful control over the bone does not necessarily predict social dominance (i.e., the ability to assert control over the behavior of littermates). Success in competition appears to reflect differences in motivation to possess and control the object (e.g., low-reward and high-reward incentive) and an ability to cope effectively under unfamiliar circumstances. One might extrapolate and predict that dogs exhibiting a high-reward incentive and history of competitive success, a low fear of unfamiliar places and novel objects, a high attraction toward familiar persons, and a high reactivity toward strangers would tend toward complete dominance, whereas dogs exhibiting a low-reward incentive and history of competitive loss, a high fear of novelty, and a high attraction toward unfamiliar and familiar persons would tend toward complete submission and dependency. Further, a history of competitive success, novelty seeking, and a reactive orientation toward strangers may predispose dogs toward social integration and extrafamilial aggression, whereas dogs with a history of competitive success, harm avoidance (bias for signals of punishment), dependency, and an attraction for strangers may be predisposed toward intrafamilial aggression and dispersal.

Collicular-Periaqueductal Gray Pathways and Reactive Adjustments

A subcortical pathway that might mediate sympathoexcitatory arousal in response to sensory input may originate in preattentive nonhabituating or slow-to-habituate collicular-periaqueductal gray (PAG) circuits. The superior colliculus (SC), an ancient midbrain structure located near the PAG, plays a central role in numerous integrative sensorimotor functions (e.g., prepulse inhibition) associated

with orienting behavior and rapid preemptive adjustments to expected and unexpected sensory events (*see Orienting, Preattentive Sensory Processing, and Visual Acuity*). Within the SC, multimodal cells responsive to visual, auditory, and tactile stimuli serve to map auditory and tactile inputs into a visuospatial coordinate system. The sensory maps represented in the SC are linked with motor maps that control involuntary eye movements and rapid preparatory motor adjustments (Dean et al., 1989). Under the influence of highly stimulating and disorderly environments, these sensorimotor processing functions may become sensitized, disorganized, and reactive. Pathways sensitized at the level of the deep SC and PAG appear to be of a nonhabituating type, perhaps due to inaccessibility by regulatory cortical networks needed to exert inhibitory control (King, 1999).

Inescapable events occurring unpredictably may be particularly prone to produce such reactive nonhabituating elaborations (e.g., noncontingent punishment), since they establish connections independent of predictive control expectancies and are perceived as inescapable. The unexpected occurrence of inescapable multisensory events involving visual, auditory, and tactile stimuli may trigger a summative effect that entrains nonhabituating reactions to the evoking stimuli present in the multisensory traumatic event. As a result of inescapability, the threat-arousing event may escalate to a defensive attack or panic, thereby integrating a deep subcortical nonhabituating circuit mediating reactive arousal and aggression. Consistent with the collicular-PAG hypothesis, the deep layers of the SC have been implicated in the expression of audiogenic "wild running" seizures resembling panic (Faingold and Randall, 1999), nonhabituating escape reactivity in response to repeated stimulation of the SC (King, 1999), and defensive behavior (Dean et al., 1989; Dringenberg et al., 2003). Stimulation of the SC via the optic nerve appears to mediate a rapid increase in blood pressure and heart rate (Cheng et al., 2001). More significantly, such stimulation also inhibits postevent vagal bradycardia—a state of sympathetic arousal consistent with the sustained activation of the flight-fight system. The SC probably contains phylogenetically conserved fields or submaps that mediate a preference for sudden change (e.g., sudden movement, looming overhead movement, loud noise, or striking/restraining actions against the body) and evoke phylogenetically prepared emergency adjustments to threatening stimuli (Westby et al., 1990). Studies investigating the electrical and chemical stimulation of the SC suggest that the area may initiate emergency motor activity and defensive behavior, perhaps involving the participation of the PAG (see Dringenberg et al., 2003). Interestingly, serotonin (5-HT) appears to exert a generalized inhibitory effect over the SC and PAG, suggesting that serotonergic medications may be particularly helpful in the treatment of reactive behavior stemming from dysregulation at the level of the SC and the PAG. Since the SC appears to play an important role in the mediation of prepulse inhibition of auditory startle (Fendt et al., 2001), dogs exhibiting reactive problems organized at the level of the collicular-PAG pathway may show sensorimotor-gating disturbances reducing prepulse inhibition to visual, auditory, and tactile startle events. Prepulse inhibition tests may be useful for identifying and differentiating such problems.

Orienting, Preattentive Sensory Processing, and Visual Acuity

The way dogs respond to fast-moving objects is probably strongly influenced by cognitive and preattentive negativity/positivity biases. The functional differentiation of cortical and subcortical processing of visual input may have significant implications with regard to how a dog responds to highly salient visual input associated with rapid movement and sudden change. Visual signals projecting from motion-sensitive receptor ganglions organized in the peripheral retina are relayed by dedicated pathways to the SC, where they undergo excitatory and inhibitory processing in preparation for the production of an orienting response or inhibition (habituation). Saccadic eye movements precede the orienting

response via a *target arc* formed between the sensory event and the frontal eye field located in the prefrontal cortex. Both the prefrontal cortex and the SC establish connections with premotor and motor nuclei in brainstem, which produce the motor signals that generate reflexive eye movements and orienting responses in anticipation of more complex behavioral adjustments.

Salient sensory input capturing attention is processed competitively based on species-typical significance and attractive/aversive (hedonic) value, with the vast majority of potential sensory events passing without notice. Out of the chaotic multitude of potential stimuli, the evocation of an orienting response signifies a selective organizing process narrowing possibility down to one orienting event and action at a time. Consequently, a sensory event may produce a saccadic alert, cause an orienting response, evoke a flinch, or release complex behavioral adjustments associated with surprise and startle (e.g., approach or avoidance). The process of selecting an appropriate response and suppressing all other responses to novelty (surprise) and sudden change (startle) is an important function of competent sensorimotor processing localized at the level of the SC and closely allied structures. As such, the SC appears to play an integrative role in organizing selective attention and sensorimotor-gating functions (e.g., prepulse inhibition) (Fendt et al., 2001), as well as mediating the expression of behavior operating under the influence of prediction-control expectancies. The SC encodes visual, auditory, and tactile sensations into multisensory maps in accordance with a visuospatial coordinate system. The resulting multisensory relations and fields are coordinated with motor reference points that initiate and guide orienting movement or complex adjustments toward sources of stimulation via the inhibitory and excitatory influences of the basal ganglia and the cerebellum (Niemi-Junkola and Westby, 2000).

In addition to conspicuous attractive and aversive events, positive and negative prediction error may increase eye movements and attentional focus on stimuli relevant to the refinement of prediction-control expectancies and the calibration of emotional establishing operations (Ikeda and Hikosaka, 2003). Prediction mismatches resulting in disappointment, threat, startle, or surprise intensify attention, evoke autonomic changes and shifts in cardiovascular activity, generate anxiety and frustration in association with behavioral conflict, and other emotional changes (e.g., anger and fear) congruent with the significance and the degree of deviation from the expected norm. These attention-activating signals enable dogs to adjust proactively and preemptively to predicted events. In reactive dogs, a preemptive and nonhabituating vigilance and anxiety bias may overshadow the acquisition of more positive expectancies toward social novelty and sudden change. Hypervigilant scanning appears to be preferentially dedicated to the detection of social objects, which are preemptively represented as potential threats (anxiety/threat bias). Vigilant scanning for social objects under an anxiety bias may essentially blind the dog to the recognition of safe social objects, thereby blocking learning that might enable it to discriminate nonthreatening social objects from threatening ones.

The dog's reactivity toward fast-moving and still objects may be linked to individual differences affecting visual acuity and discrimination ability. In addition to the influence of retinal variations on vision (e.g., size and complexity of the visual streak and central area) (see *Retina* in Volume 1, Chapter 4), dogs vary considerably in their ability to process visual information due to other causes. For example, to see clearly, the object image must be focused on the retina—not behind or in front of it, as in farsightedness and nearsightedness. One study examining the eyesight of German shepherds and Rottweilers found that more than half of the dogs tested were nearsighted (Murphy et al., 1992). Nearsightedness impairs a dog's ability to see objects detected at the *alert distance*, perhaps predisposing such dogs to respond to such events as intrinsically ambiguous and uncertain. With respect to objects that are located nearby within the *startle distance*, a dog's ability to form accurate retinal images rapidly decreases as the object moves within 20 to 13

inches away from the retina; objects (e.g., a child's face) viewed at a point closer than this focusing range may be blurred and require other senses to facilitate recognition (e.g., olfaction, hearing, and touch) (Miller and Murphy, 1995). Dogs expressing a sparsely enervated central area may be especially impaired in their ability to recognize nearby faces. Dogs with poor vision may rely on established expectancy biases to process the uncertain events, resulting in friendly acceptance or possibly a bite in the face. Casual tests (e.g., dropping small treats on the ground, throwing a ball, or tossing a toy or treat for the dog to catch) can give the trainer a rough idea of visual function; however, a veterinary ophthalmic examination should be performed in dogs suspected of exhibiting a possible visual impairment in association with reactive behavior.

SOCIAL ENGAGEMENT AND ATTUNEMENT

According to Porges (2001), the visual communicative facial and head movements that are exchanged during social engagement are mediated by a network of cranial nerves operating under the regulatory control of corticobulbar pathways and special visceral efferents originating in the ventral vagal complex (VVC). The VVC is a relatively recent mammalian adaptation, enabling social animals to match autonomic arousal levels to complex social exchanges and transactions. The VVC consists of the myelinated vagus nerve, the nucleus ambiguous, and the source nuclei of the social engagement system (SES). Prosocial interaction perceived as safe appears to activate the mammalian SES, producing a lowered heart rate and a general calming effect, whereas threatening or challenging social exchanges result in the retraction of the SES and the activation of disengagement or confrontational systems.

Whereas wiggle dancing and animated tail wagging are indicative of social confidence and friendliness, a lowered tail held stiffly between the legs indicates a state of apprehension and reserve. Similarly, an elevated head position is indicative of an excited and bright mood, whereas a lowered head position or *hangdog* look is associated with a dark mood (dysthymia). These sorts of kinesic indicators of emotion and mood combine in almost endless ways to communicate a wide range of social messages while mediating autonomic attunement or misattunement. The differential showing and concealment of the white of the eyes and teeth appears to be used by dogs to convey a wide range of signals while modulating social stress (see DeVries, 2003). Many of these signals are extremely subtle and brief and may pass unnoticed (e.g., winking) but may nevertheless exert variable antistress and autonomic attunement effects. For example, cow-eyed gazing in which the white of the eye is slightly shown in association with bright glistening eyes appears to signify contented and focused affection, whereas exposure of large portions of white with anxious staring and nose licking appears to reflect a highly stressful state. Fang flashing (a quick and subtle expression of social anxiety in which a fang is briefly bared) usually anticipates uneventful and nonthreatening *cutoff* transitions, whereas baring of the teeth into a steady agonistic pucker obviously conveys a significantly different message. Numerous subtle licks and slurps, grunts and sighs, or chomping or clacking noises, especially at the conclusion of certain yawns, appear to signify frustration at waiting or other delays. The steady expiration that occurs when a dog growls may exert a vagal braking effect on autonomic arousal that permits the target to move away safely, whereas the extended expirations associated with howling or whining may stabilize autonomic arousal and enable the dog to cope with confinement or restraint preventing it from gaining access to the attachment object while signaling the attachment object to come to its rescue.

Many of these social behaviors and displays appear to be used in coping with domestic interactive stress with the apparent goal of integrating social relations and attachments conducive to autonomic regulation. In contrast to constructive social exchanges, dogs showing social signals signifying a serious intent to attack, thereby precluding or terminating attachment relations, show a loss of

facial expressiveness and warmth, exhibiting a deadpan look of utter seriousness and determined resolve, backed by a steady and unflinching stare that locks on the target in an utter readiness to attack (Figure 8.1). In contrast to the flat, expressionless appearance of dogs preparing to attack, dogs prepared to engage in friendly social behavior express their intent with an invigorated and sustained attention (e.g., eye contact and social head tilt), intensified social engagement (e.g., jumping up), or displays aimed at evoking play (e.g., play bow and face). These various social behaviors are mediated in association with preemptive and preparatory arousal that reflects varying degrees of sympathovagal balance or imbalance and allostatic load resulting from attachment dynamics.

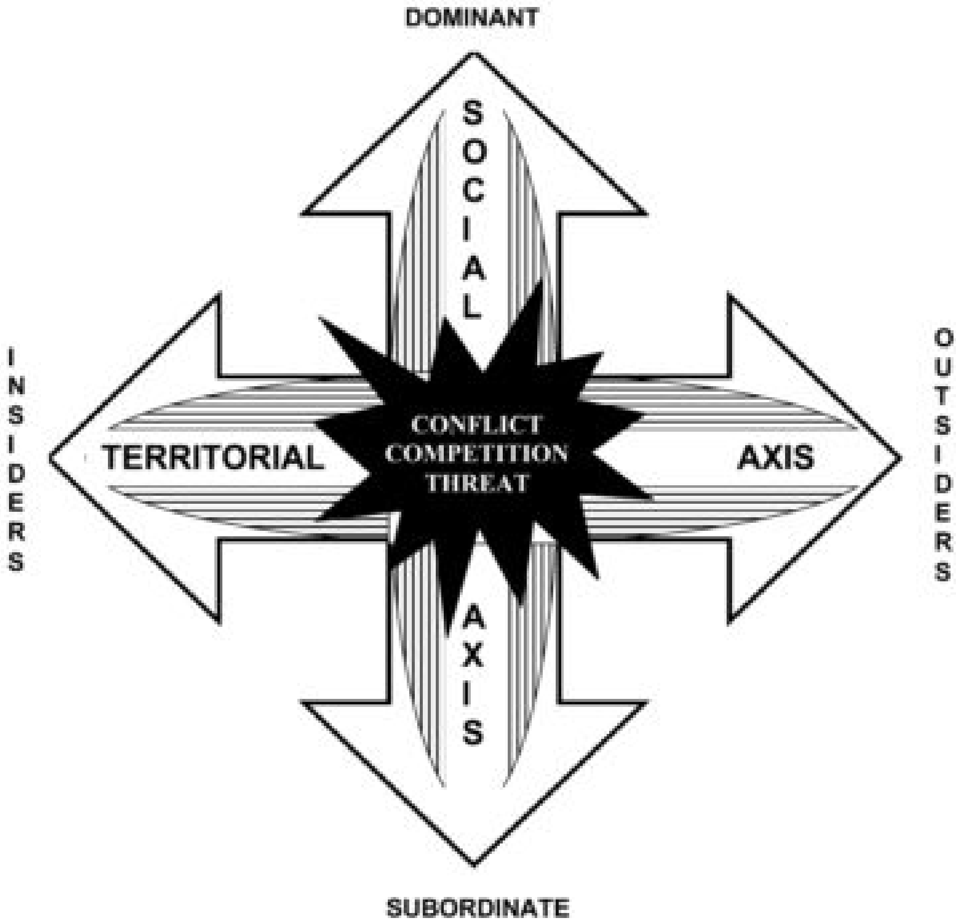

FIG. 8.1. Dominance hierarchy and territory serve complementary functions with regard to the regulation of aggression between conspecifics. The social distance between group members is achieved by means of vertical, hierarchical spacing via the establishment of social rank. Territory, on the other hand, defines the horizontal, physical space existing between competing groups. Whereas the dominance hierarchy is concerned with the regulation of aggression between group members, territory limits hostilities between members of competing groups. As a result, social dominance and territorial imperatives appear to share a common functional axis based on the need to establish cooperative group activity and to promote peaceful coexistence between neighboring conspecific groups.

The social head tilt is a distinctive canine social display of considerable interest. The social head tilt most often occurs in situations involving anticipatory excitement and intensified interest in the significance of the owner's vocalizations. Socially apprehensive and reactive dogs do not appear to exhibit the head-tilt response to human vocalization and generally show reduced capacities for sustained eye contact and other activities requiring social attention skills. Francis Barraud's famous painting, *His Master's Voice*, Nipper the dog is captured with his head cocked to the side in a rapt moment of looking intently into the horn of a phonograph. The action of tilting the head appears to be integrated at the level of source nuclei in the nucleus ambiguus that control the muscles of the middle ear and various expressive facial and head movements used to initiate and sustain social engagement (Porges, 2001). The middle-ear muscles are hypothesized to aid in extracting useful acoustic information from complex sources of auditory stimulation. The neural control of the middle-ear muscles is also linked with the regulation of facial expression, gaze, and vocalization. When the dog tilts its head, it may be attempting to concentrate on vocal sounds to identify familiar words and intonations associated with some anticipated activity. Gazing and talking to a dog in a manner that evokes a head tilt exerts a strong activating effect on the canine SES. The head-tilting behavior appears to be most robust in cases where the dog shows excitement and anticipation about something being said, suggesting the possibility that the head tilt may serve to help modulate arousal in situations of building anticipation and excitement. Sustained attention and evocation of head tilting, social gazing, talking, and other expressive movements of the face and head may exert a highly desirable invigorating effect on the SES while enhancing parasympathetic regulation over impulsive arousal. The intensified social gaze and attention associated with the head-tilt response should receive careful study as a conduit for social learning and the integration of secure attachments and autonomic attunement.

Oxytocin, Arginine Vasopressin, and Autonomic Attunement

Consistent with the autonomic regulatory function of social communication and engagement, oxytocin and AVP appear to play important roles in assessing the relative safety or danger posed by social situations. The social recognition and calming effects mediated by oxytocin probably play a central role in activating the VVC, promoting social engagement and attachment, and supporting group cohesiveness. Conversely, AVP may promote a bias of social anxiety and danger, especially when its release is triggered by ambiguous or uncertain situations in association with CRF while social repulsion or nervous social attachments are being mediated. A study involving humans is interesting with respect to a possible role of AVP in the discrimination of ambivalent social facial expressions (Thompson et al., 2004). Experimental and control subjects showed little change in their attentional or autonomic responses when shown photographs of neutral, happy, or angry facial expressions; however, subjects given nasal AVP showed a significant change in the activity of the corrugator muscle in response to neutral facial expressions. The corrugator muscle, located above the brow, is involved in the expression of anger. The authors suggest that the increased corrugator activity may indicate that AVP mediates an aggressive bias in response to neutral and ambiguous social facial expressions. In contrast, oxytocin appears to mediate an antistress bias of anticipated comfort and safety when exposed to social ambiguity and uncertainty (Windle et al., 1997; Uvnäs-Moberg, 1998).

AVP and oxytocin play important regulatory roles in the adaptive attunement of cardiovascular function to environmental and social threats and challenges. Central oxytocin mediates a slowing of the heart rate by increasing vagal tone via projections to the dorsal motor nucleus of the vagus (DMV), whereas AVP increases heart rate via projections to the nucleus of the solitary tract (NTS), probably via inhibitory pathways targeting GABAergic parasympathetic neurons (Wang et al., 2002). Whereas oxytocin

appears to produce a calming antistress effect via repeated exposure to social stimuli producing comfort and safety, AVP appears to mediate a self-protective vigilance in response to repeated exposure to social threat and loss. Oxytocin appears to switch on the SES as the result of interaction perceived as safe (Porges, 2001), whereas AVP appears to toggle off the SES and switch on the sympathetic-adrenomedullary system (SAM) in response to social challenges and threats (see Sewards and Sewards, 2003). The SAM system is phylogenetically older than the social engagement system. The passive response to defeat appears to be mediated by the dorsoventral vagal complex (DVC), which is described by Porges as a vestigial immobilization system and regarded as the most ancient of the mammalian arousal control systems. The DVC probably plays a prominent role in learned helplessness. The dynamic influences of AVP and oxytocin on cognitive, emotional, and social activity suggest that the neuropeptides perform integrative roles in the organization of behavior, perhaps via the activation of survival modes and modal strategies (see *Survival Modes and Allostasis*). AVP has been demonstrated to play a prominent role in the expression of territorial marking and aggression in hamsters (see *Arginine Vasopressin and Aggression* in Volume 1, Chapter 3), but its effects vary considerably from species to species, even closely related ones. For example, whereas AVP increases both intermale aggression and affiliative behavior in monogamous and nonterritorial prairie voles, it does not produce these effects in nonmonogamous and territorial montane voles (Young, 1999).

Arginine Vasopressin, Hyperkinesis, and Aggression

Although an overactive HPA system (allostatic hyperdrive and high cortisol) may mediate a disorganizing effect on a dog's ability to cope adaptively with social stressors, playing a major role in the elaboration of reactive aggression, other lines of research suggest that an underactive HPA system (allostatic hypodrive and low cortisol) may increase the individual's vulnerability to show impulsive aggression (see *Stress, Low Cortisol, and Aggression* in Chapter 6). Hypocortisolism may diminish adrenal feedback restraint over central AVP and CRF and trigger a variety of endocrine disturbances and behavioral changes associated with impulsivity (see *Stress, Low Cortisol, and Aggression* in Chapter 6). Children with attention-deficit hyperactivity disorder (ADHD) in combination with comorbid oppositional defiant disorder (ODD) exhibit reduced salivary cortisol levels in comparison with children not affected by ADHD (Kariyawasam et al., 2002). The difference, however, was only significant among a subgroup of ADHD children not taking stimulant medications, suggesting that stimulants may serve to normalize HPA-system tone. Among dogs, low plasma cortisol has been shown to elevate AVP and CRF (Papanek and Raff, 1994), perhaps representing a significant link between low-cortisol activity and autoprotective aggression (see *Arginine Vasopressin, Testosterone, and Serotonin* in Chapter 6). Sewards and Sewards (2003) formulated a model of defensive behavior and aggression based on the activating effects of CRF and AVP. Whereas central and peripheral CRF concentrations are postulated to trigger the defensive autoprotective mode, the central concentration of AVP is proposed as the primary trigger entraining the offensive autoprotective mode. A significant correlation between AVP and a life history of aggression has been established in humans (Coccaro et al., 1998), suggesting the possibility that a similar correlation may exist in dogs. Elevated CRF augments norepinephrine (NE) activity via the stimulatory action of CRF at the locus coeruleus (LC), leading to increased vigilance and sympathetic arousal. Dogs stimulated to induce anger show an increase in adrenal NE, whereas fearful dogs show a relative increase in adrenal epinephrine release (Verrier and Dickerson, 1991). Chronically blunted HPA activity may also gradually disrupt endogenous opioid restraint over CRF activity (Valentino and Van Bockstaele, 2001) or diminish 5-HT_2-mediated modulation of NE neurons (Done and Sharp, 1994). In addition to mediating an increased release of proinflammatory

cytokines, reduced cortisol levels have been linked with decreased heart-rate variability (HRV) in response to mild stress (Kunz-Ebrecht et al., 2003)—a diagnostic indicator of sympathovagal imbalance.

Increased AVP appears to elevate baroceptor set points significantly while reducing vagal tone (Michelini, 1994), a permissive cardiovascular background compatible with impulsivity and a reactive coping style. Corson and colleagues (1980) found that hyperkinetic dogs show various signs of *visceral turmoil*, including increased AVP release, rapid heart rate, panting, profuse salivation, and stimulant-responsive forms of impulsive aggression. This pattern of hyperexcitability and impulsivity in dogs was first observed and described by Pavlov (1928). He found that certain dogs exhibited spontaneous and constant salivation while restrained in the experimental harness. In addition, these dogs exhibited persistent efforts to escape and showed learning and appetitive disturbances—behaviors that Pavlov attributed to the frustration of an overresponsive freedom reflex:

> The conditioned reflex formed slowly, remained weak, and always fluctuated. The spontaneous salivary secretion continued, and gradually increased with each experimental séance. Also the animal constantly moved, struggling in every possible way in the stand, scratching the floor, and pulling and biting at the frame, etc. This was accompanied by dyspnea, always increasing toward the end of the experiment. (283)

Impulsive aggression associated with AVP-mediated antidiuresis and hyperkinesis has been successfully treated with stimulants (see *Two Case Histories* in Volume 2, Chapter 5, and *Pharmacological Control of Hyperkinesis* in this volume, Chapter 5). Stimulant therapy may be particularly useful in the treatment of impulsive aggression in association with severe socialization and habituation deficits (Corson et al., 1980).

STRESS, THYROID DEFICIENCY, HYPOCORTISOLISM, AND AGGRESSION

The chronic stress associated with social ambivalence and entrapment may profoundly affect neurophysiological substrates mediating the organization of canine coping styles. Stress-related modifications of 5-HT, dopamine (DA), and NE systems can exert pervasive effects on mood, attachment, and impulse control. In addition, the dysregulation of the HPA system may predispose dogs to develop a variety of behavioral and immunological disturbances (Padgett and Glaser, 2003). Changes affecting the immune system appear to be sensitive markers of stress. For example, salivary immunoglobulin A (IgA) levels have been shown to be an accurate indicator of acute stress reactivity in dogs (Kikkawa et al., 2003), with low IgA levels indicating a stressful state of arousal (e.g., exposure to the sound of vacuum cleaner), whereas elevated IgA levels may be indicative of a confident and adaptive orientation to novelty (Skandakumar et al., 1995). Another potentially useful physiological marker associated with immunological impairment (Muldoon et al., 1997), psychological distress (Chen et al., 2001), and impulsivity is cholesterol level (see *Fat, Cholesterol, Fatty Acids, and Impulsive Aggression* in Chapter 7). Penturk and Yalcin (2003) have reported that dogs with serious aggression problems show significantly lower total cholesterol and triglyceride levels than do nonaggressive controls. In combination with other diagnostic tools, IgA and cholesterol panels may provide useful indicators for exploring etiologies of stress-related behavior problems and refining treatment protocols.

Stressful conditions also appear to exert a dysregulatory effect over thyroid activity. In addition to metabolic regulatory functions, the thyroid appears to exert far-reaching influences on development and behavior (Meaney et al., 1987; Anderson, 2001). Subclinical disturbances in thyroid function have been linked to the etiology of a number of canine behavior problems, including impulsive aggression (Reinhard, 1978; Dodds, 1992; Fatjó et al., 2002). In addition to the adverse effects of chronic and acute stress, thyroid levels may be blunted by environmental contaminants, diet, and age (Reimers et al., 1990; Crockford, 2003). Strong evidence suggests the possibility that thyroid function may be

adversely affected by immune reactions produced by vaccinations (Scott-Moncrieff et al., 2002). After receiving vaccinations, antithyroglobulin antibodies are elevated, with some dogs showing concentrations comparable to the range observed in autoimmune thyroiditis. Whether these antibodies induce thyroiditis and damage thyroid function has not been demonstrated, but such an iatrogenic effect may be a real risk in susceptible dogs (Dodds, 2001). Hypothyroidism is the most commonly diagnosed canine endocrine disease, with at least half of all cases attributed to autoimmune thyroiditis (Scott-Moncrieff et al., 2002).

Impulsive aggression with subclinical hypothyroidism appears to occur most commonly with indicators of cognitive disturbance and may affect older dogs that were previously nonaggressive. Such dogs may show a heightened aggressive reactivity in response to unwelcome social interaction having an ambiguous character or seem to bite out of the blue. Among rats, antidepressant drugs have been found to increase thyroid concentrations selectively in the amygdala (myelin fraction), in contrast to other brain areas, which showed no significant change (Pinna et al., 2003). These findings suggest the possibility that the critical target site for the action of thyroid on behavior may be through the amygdala, a hypothesis consistent with certain types of attacks against familial persons in which the dog may fail to recognize the victim or misinterpret the significance of the person's actions. For example, the role of the amygdala in face recognition and the decoding of the emotional significance of facial expressions is consistent with the tendency of some of these dogs to snap at the face of familiar persons. Chronic stress putting the HPA system into allostatic hyperdrive and resulting in elevated plasma glucocorticoid levels may blunt thyroid activity, perhaps via glucocorticoid receptors expressed by thyroid-releasing hormone (TRH) cells in the hypothalamus (Swaab et al., 2000). On the other hand, hypocortisolism and allostatic hypodrive may also blunt thyroid function via autoimmune disease and thyroiditis (Tsigos and Chrousos, 2002). A possible linkage between hypocortisolism and hypothyroidism has been reported in Leonbergers (Smallwood and Barsanti, 1995). In addition, the incidence of hypoadrenocorticism (Addison's disease) appears to be relatively high in bearded collies (Sells, 1996; Oberbauer et al., 2002), a breed that shows a broad spectrum of behavior problems in association with thyroid deficiency and hypothyroidism, including aggression (Hamilton-Andrews et al., 1999). Although hypoadrenocorticism is regarded as a rare canine endocrinopathy (Peterson et al., 1996), subclinical hypocortisolism may be more common than commonly assumed. Plechner (1976 and 2003) has suggested that hypocortisolism is underdiagnosed and that dogs are afflicted by an incompletely understood polyglandular endocrine disorder that results in a chronic cortisol and thyroid insufficiency. In addition to producing too little cortisol, the adrenal cortex of affected dogs may release excessive sex prohormones in response to dysregulated adrenocorticotropic hormone (ACTH) levels. According to Plechner's hypothesis, plasma estrogens synthesized from these adrenocortical prohormones in turn bind with circulating thyroid (T3/T4) to further augment a health-threatening endocrine imbalance. Plechner claims to have treated 50,000 dogs and cats with a low-dose regime of glucocorticoid and thyroid replacement therapy but provides little documented evidence in support of his hypothesis. Nevertheless, given the apparent role of low cortisol and thyroid in the etiology of certain forms of impulsive aggression, more routine testing of thyroid, cortisol, and immunoglobulin levels (IgA, IgG, and IgM) should be performed in aggressive dogs.

A number of commonly used drugs (e.g., aspirin, diazepam, phenobarbital, and prednisone) have been reported to blunt thyroid activity in dogs (Ferguson, 1984; Daminet and Ferguson, 2003). Thyroid disturbances have also been linked to phenothiazines (e.g., chlorpromazine) and psychotropic drugs (Sauvage et al., 1998). Tricyclic antidepressants (e.g., amitriptyline and clomipramine) appear to produce a significant blunting effect on thyroid activity. A recent study found that clomipramine reduced T4 levels by 35% in

dogs over a 4-month treatment period (Gulikers and Panciera, 2003). The behavioral effects of such a reduction in thyroid activity are unclear, but they may be potentially problematic in dogs already showing compromised thyroid function or in dogs being treated for behavior problems with the antidepressant drug. Dogs exposed to long-term clomipramine treatment may be at an increased risk of developing thyroid-related anomalies, perhaps recommending that thyroid levels be monitored and appropriate actions taken to prevent thyroid-related problems from occurring secondary to clomipramine therapy (e.g., thyroid supplementation).

Diminished thyroid activity may reduce the efficacy of antidepressant drugs for controlling behavior problems in dogs, a problematic effect observed in human patients treated for depression (Henley and Koehnle, 1997; Cole et al., 2002). Several reports have noted the beneficial effects of combining thyroid with antidepressants to augment their effect. Interestingly, the tricyclic antidepressant imipramine, when given in conjunction with T3, exerts a significant down-regulating effect on the 5-HT_{2A} receptors (Moreau et al., 2001). According to Henley and Koehnle (1997), the low dosages of thyroid used to augment antidepressant effects in humans do not pose a significant risk of inducing a state of hypermetabolism. These observations suggest that CDA nonresponders to antidepressant therapy may benefit from a treatment program that includes low-dose thyroid. Given the apparent side effects of clomipramine therapy on thyroid function, together with the potential synergistic effects of giving the two medications together, it seems like a natural combination in the treatment of certain behavior problems.

Activity Success and Failure, Pavlovian Typology, and Coping Styles

Activity success in obtaining nurturance during early development may predispose puppies toward extraversion and fearlessness, active modal strategies (seeking and exploring), excitability, curiosity, playfulness, confidence, and social dominance, whereas social interaction resulting in activity failure may predispose the puppies toward introversion and fearfulness, passive modal strategies (waiting and hesitation), inhibition, insecurity, and social subordination. Both extraversion and introversion mediate adaptive social coping styles comparable to Pavlov's sanguine (s) and phlegmatic (p) types. The stability of these types depends on the support of secure social and place attachments (autonomic attunement) formed by social exchanges promoting comfort and safety (somatic reward) and the avoidance of loss and risk (p type), together with sufficient variability, flexibility, and novelty to support surprise via cortical reward (s type). The association of behavioral success with surprise, cortical reward, and increased active modal activity is consistent with Brace's (1962) notion that the differentiation of dog behavior is mediated by two primary behavioral traits—*activity success* and *general activity*—which can be conveniently collapsed into a single supertrait referred to as *activity-success seeking* (extraversion). Svartberg and Forkman (2002) have reported evidence that seems to support such a temperament-organizing supertrait associated with activity success and closely resembling extraversion. According to cynopraxic training theory, the invigoration of active modal strategies (e.g., seeking, investigating, exploring, and risk taking) via cortical reward (surprise) evokes elation and increased modal activity (extraversion dimension), whereas somatic reward (comfort or safety) and the emergence of passive modal strategies (e.g., waiting, hesitating, ritualizing, and risk-avoiding behavior) mediate calming, inhibition, and decreased activity levels (introversion dimension). The adaptive canine personality consists of a balance of s-type and p-type characteristics organized in the process of integrating autonomic attunement and secure social and place attachments. Social interaction conducive to autonomic attunement depends on an adaptive coping style shaped in accord with a principle of fairness and mutual activity success.

Broadly speaking, these observations suggest that the differentiation of s-type and p-

type characteristics is the result of changes flowing from social interaction promoting a perception that significant events are controllable by means of cooperation and that cooperative social exchanges are fair, whereas reactive dogs, corresponding to Pavlov's choleric (c) and melancholic (m) types, are differentiated by social exchanges that result in a perception that significant events are uncontrollable and that social exchanges are unfair. Reactive dogs are hypothesized to express two general reactive coping styles in response to social and environmental novelty and sudden change: (1) c-type dogs (unstable extraverts) combine a bold (fearless) bias toward novelty (neophilia) with risk taking, (2) m-type dogs (unstable introverts) combine a shy (fearful) bias toward novelty (neophobia) with risk avoidance (see *C-type and M-type Affinity for the Flight-Fight System* in Chapter 7).

C types are further differentiated into socially obtrusive and exploitative dogs driven by impulsive social and environmental seeking activities (exploiters), on the one hand, and socially impulsive and reactive dogs operating under the influence of autoprotective power-dominance motivations (despots), on the other. The lack of autonomic attunement resulting from social exchanges and transactions perceived as fair is an important source of impairment for reactive dogs. The autonomic attunement promotes selective and sustained attention, emotional autoregulation, and impulse control. Without the autonomic attunement afforded by the integration of secure attachment, a dog's ability to regulate impulsivity and reactive behavior competently is significantly degraded. Instead of hesitating and responding in accord with control modules and adaptive modal strategies, bold c types appear to perceive social novelty and sudden change as signals to prepare for uncontrollable appetitive or challenging events, causing them to orient in a state of preemptive readiness to exploit or confront under the invigoration of state anger (anticipatory frustration/irritability). Whereas exploiters are driven to get more, despots are driven to get and keep what they take. The presence of trait anger, reduced fear, and avidity for risk taking make c-type despots potentially dangerous (see *Flexible versus Rigid Watchdog Scripts*). M types are differentiated into socially hesitant and insecure dogs that are anxious and avoidant of social contact and emotionally withdrawn, depressed, or helpless. Whereas c-type dogs are driven to get and keep under the preemptive influence of exploitative motivations and autoprotective power-dominance motivations (trait anger), m-type dogs are driven to escape and avoid harm under the preemptive influence of autoprotective vigilance and readiness to flee (trait anxiety). Dogs expressing nervous attachments (autonomic dysregulation) show variable amounts of c-type and m-type behavior, with specific attributions based on the presence of trait anger (c type) and trait anxiety (m type) and behavioral threshold shifts resulting from social interaction producing state anxiety or anger. Under the influence of social interaction inducing anxiety (attention disengagement), c-type dogs may integrate m-type characteristics conducive to panicogenic arousal and impulsive aggression; on the other hand, m-type dogs may integrate c-type characteristics under the panicogenic influence of state anger (social disengagement) triggering catastrophic arousal and reactive aggression.

Activity success is capable of significantly altering general activity levels via the effects of cortical (elating) and somatic (calming) reward. In a sense, these two prominent types of reward can be characterized as expressing energy-expending and energy-conserving coping styles, orientations that may shift in accordance with social or environmental changes that favor expending energy to obtain an advantage at some risk or conserving energy to maintain known resources and avoiding disadvantages as the result of loss or risk. Finally, puppies showing s-type temperaments tend to be playful and independent, whereas those showing a p-type temperament tend to be affectionate and dependent. The significance of independence for developing puppies is linked with the formation of prediction-control expectancies and learning to adjust behavior in accordance with positive and negative prediction error, fair-play exchange, and autoattunement rather than merely seeking and receiving comfort and safety from a surro-

gate maternal object. The s-type orientation toward social independence, playfulness, exploratory curiosity, and spontaneity is probably strongly influenced by the quality of maternal care and the formation of secure attachments. The p-type orientation involving reduced playfulness, greater social dependency, increased affection and contact seeking, avoidance of risk, and reactivity toward ambiguous social stimuli reflects social and cognitive adjustments associated with the integration of insecure attachments. The vast majority of dogs express and merge both s-type and p-type characteristics while adapting to the social demands of domestic life. These changes are mediated via the differential inhibitory and excitatory influences of adaptive anxiety and frustration on behavior. An important goal of cynopraxic therapy is to balance and integrate s-type and p-type traits systematically. The canine personality is perfected by social interaction that promotes fairness while facilitating secure attachments (autonomic attunement), affectionate playfulness, mutual appreciation, and interactive harmony.

Proactive versus Preemptive Processing and Cynopraxis

Dogs operating under the influence of a reactive coping style respond preemptively and incompetently to social novelty and unexpected change as representing relatively uncontrollable opportunities, challenges (loss), or threats (risk), whereas dogs exhibiting an adaptive coping style tend to respond to similar circumstances under a preemptive bias of confidence and alertness for signals of reward. As the result of a history of activity success, adaptive dogs appear to acquire a buffer of tolerance or *adaptive optimism* that enables them to cope more effectively with uncertainty. Both strategies are subject to error, but whereas adaptive dogs tend to adjust to error in a proactive way, reactive dogs tend merely to react to error without learning from it. To borrow Rotter's terminology (see *Locus of Control and Self-efficacy* in Volume 1, Chapter 9), reactive dogs are external-type learners that respond impulsively, helplessly, or fearfully to perceived opportunities, challenges, and threats under a bias of event uncontrollability and uncertainty/danger, whereas adaptive dogs are internal-type learners that cope with change and novelty under a bias of event controllability and safety via the organization of prediction-control expectancies, calibrated establishing operations, and adaptive modal strategies.

The approach of a stranger appears to set off a three-way race between seeking-mode processing, flight/fight-mode processing, and stop-mode processing (Band and Van Boxtel, 1999). What a dog ultimately does is largely determined by the system that finishes processing operations first. If reactive processing is completed before stop-mode processing is finished, the flash point of no return may be reached, causing the flight or fight adjustment to escape from inhibitory control. The decision to exploit, attack, hold ground (engage in conflict behavior), or retreat is determined by reactive behavioral thresholds, ongoing arousal, and inhibitory coping skills. With increasing appetitive arousal the dog is likely to approach and exploit the object; with increasing fear the dog is likely to feel threatened and try to escape; whereas with increasing provocation the dog is more likely to confront the unfamiliar person. On the other hand, if the inhibitory stop processing is completed first, the reactive flight/fight-mode processing may be brought to a halt (all-stop signal) or after interrupting flight-fight processing an incompatible approach response may be produced (stop-change signal). Since the reactive response becomes progressively more difficult to cancel as reactive processing nears the point of no return, it is critical that stop-change processing be initiated at the earliest stage in the race.

Unfortunately, reactive dogs are problematic in this regard, since subcortical flight-fight processing networks may be maintained in a tonic state of preparatory arousal (vigilance and readiness to react) under the influence of reactive sympathovagal deregulation (sympathetic dominance), priming preattentive auditory, visual, and motor systems to process and respond to novel and ambiguous social signals with a negativity bias that causes the dog to perceive the developing situation as an signifying an uncontrollable challenge or threat. Pre-

emptive amygdalar activation (autoprotective anticipatory anxiety) stemming from aversive and traumatic emotional learning resulting from threatening events perceived as inescapable may support a chronic state of autonomic disturbance and nervous attachments that are incompatible with effective inhibitory stop or stop-change processing and social engagement. The preattentive and preemptive nature of reactive adjustments serves to support a tonic state of autonomic deregulation in support of a heightened state of vigilance and reactive readiness—changes that may require specialized cynopraxic procedures (e.g., target-arc training) to reboot and restore competent preattentive functions. A central goal of cynopraxic therapy is to integrate secure social and place attachments and autonomic attunement incompatible with reactive behavior. Together with the emergence of secure attachments and attunement that enable the dog to independently autoregulate sympathovagal tone conducive to an adaptive coping style, a number of bond-promoting quality-of-life changes are simultaneously introduced to activate survival modes conducive to social exploration and play. However, insofar as interactive conflict persists in the household, the amygdalar autoprotective circuits previously mentioned will remain active. Consequently, an important part of the cynopraxic process is ICT, with the goal of identifying sources of conflict, building a training space around them, and converting conflictive reward interests into shared opportunities for mutual reward based on fair-play cooperation and compromise, thereby systematically reducing social ambivalence and entrapment dynamics while increasing mutual appreciation and interactive harmony.

With the emergence of autonomic attunement, the dog transitions out of impulsive gratification to seeking activities organized to produce somatic reward, that is, outcomes promoting comfort and safety. The refinement of autonomic attunement is critically important for the experience of both somatic reward and cortical reward. Initially, surprise promotes exploitative modal activity that rapidly spirals into disappointment and loss. Within the context of an adaptive coping style, disappointment depresses modal excess (mania) and integrates passive modal strategies such as hesitation and delay of gratification, which, in turn, set the stage for better-than-expected outcomes and active modal activity that becomes increasingly focused, investigative, and experimental. These changes in active and passive modal behavior reflect a further refinement of autonomic balance, the organization of which moves the dog from manic excitement to elation. A similar shift toward stability occurs in passive modal adjustments, with the dog learning to process disappointments as information obtained while optimizing discovery, instead of reactively responding to them as threatening obstacles. Passive modal strategies enable the dog to seek, explore, and investigate without unduly sacrificing or risking loss of comfort and safety. Affectionate transactions and play gradually become the primary focus of cynopraxic therapy as a foundation of secure attachments is established. The balancing effects of affection and play on autonomic functions are profound and appear to open a healing space from where human-dog companionship facilitates a heightened state of well-being and mutual appreciation referred to as *cynopraxic joy*. As autonomic attunement becomes clarified and precise, human-canine interaction appears to become increasingly spontaneous, playful, and creative: liberated. The elation of discovery may now slowly or precipitously transition into the joy of becoming—a transition marked by a playful acceptance and rejoicement in the aleatory nature of life—and herald the opening of a paradoxical play space. Instead of seeking reward in prediction error or optimized control, the direct experience of ambiguity and uncertainty becomes the object of appreciation infusing everyday activities with a quiet sense of affectionate playfulness and freedom—a state of innocence that radiates from the heart of the dog as beacon for human betterment.

Barking, Motor Displays, and Autonomic Arousal

Whereas threat barking and piloerection may be used to advertise threats at a distance, the

growl is usually reserved for making threats at close quarters (Bleicher, 1963). Alarm and threat barking appears to be performed to affect the behavior of the intruder at a distance as well as to alert group members and to draw their attention to the situation (see *Behavioral Effects of Domestication* in Volume 1, Chapter 1). In addition to performing a coordinated defense function by alerting and arousing group members to a potential threat, barking may ward off intruders, perhaps causing them to avoid the area in the future. Alarm and threat barking may be rewarded by attracting the attention of family members or by stimulating the barking of other dogs (social contagion effect). Threat barking may also be rewarded by its ability to cause the intruder to withdraw from the defended area. Alarm and nuisance barking may be stimulating and intrinsically rewarding for some dogs. Motor displays are coordinated with barking threats, perhaps with the goal of disambiguating the dog's intent and strengthening the overall impression. The dog may thrust its front feet into the ground, giving the impression that it is straining to hold itself back, perform lateral shunts over a wide expanse of turf, intermittently charge forward and turn sharply about to snap angrily at the tail, and show a variety of threatening and shifting signs of intent indicative of reactive arousal. However, the most serious threat is a hard-to-describe but unmistakable "sick with repugnance look" that may present with some threat barking or other more subtle signs of aggressive intent.

The acoustics of barking vary according to context, type of provoking stimulation and arousal, and developmental factors (Bleicher, 1963). When responding to disturbances provoking alarm and aggressive arousal, individual barks are lower pitched, last longer, and are more rapidly repeated than barks associated with isolation and play (Yin, 2002). Alterations in respiration associated with different vocalization patterns may exert signature vagal effects on arousal levels via sinus arrhythmias. During inspiration, heart rate tends to increase whereas with expiration heart rate tends to decrease. These sinus arrhythmias are most evident while the dog is resting and reflect influence of breathing on vagal tone. The repetitive action of barking may modulate defensive arousal via afferent vagal feedback on forebrain and midbrain areas. The pressure and forceful cadence of threatening barking rhythms may contribute to the maintenance of a high level of state arousal and readiness, whereas the steady diaphragmatic pressure associated with whining and howling may serve to moderate or reduce emotional distress. This hypothesis suggests that canine vocalizations not only serve a communication function, but may also modulate the signaler's emotional state via a vagal mechanism. For instance, the squeak or yelp in response to unexpected discomfort may circumvent a reflexive aggressive response via rapid vagal feedback on aggression-mediating pathways. As such, the yelp appears to represent a bidirectional inhibitory stop signal, acting both internally and externally on the social source of aversive stimulation. Instead of attacking the source of discomfort, the well-socialized dog tends to respond to such events by yelping, thus appearing to give the doer of the aversive action the benefit of doubt.

The confrontational intent of the aggressive dog is accented by direct eye contact and pupillary dilation. Intent may be signaled at intermediate distance by a stiff gate and erect posture augmented by a bristling of hackles on the neck and along the back. Piloerection is mediated by sympathetic enervation of smooth muscles (arrector pili) attached to hair follicles. The contraction of arrector pili causes the hair shaft to stand up. Hackles make a dog look bigger and more formidable, perhaps increasing the dog's resource-holding potential and serving to intimidate a potential adversary. Unlike pupil size changes, which are under the combined influence of both sympathetic and parasympathetic control, piloerection is under the exclusive control of the sympathetic nervous system (SNS). Skeletal muscle tone and plantar sweating (indicated by sweat marks left on flooring) are useful markers of sympathetic arousal in dogs.

Dogs appear to organize a schema of safe and familiar expectancies that determines

whether they initiate friendly social engagements. In addition to barking at the approach of people and other dogs, dogs bark in response to unexpected stimulus change or mismatches between the usual or safe schema and an unexpected change (Adams and Johnson, 1995). The various mismatches between social and environmental stimuli and the accustomed safe and familiar expectancies of them produce varying levels of uncertainty, producing alarm, uncertainty, threat, and challenge. Alarm in response to environmental or social novelty and uncertainty may increase progressively or catastrophically, to borrow Zeeman's (1976) term, depending on the size and suddenness of the mismatch between the event and the familiar schema. Further, alarm barking may be evoked by the startle of sudden change or as a threat in response to a perceived challenge posed by the approach of an unfamiliar person. Threat barking is probably associated with an approach-avoidance conflict triggered by the approach of a stranger or the occurrence of a sudden change (e.g., strange sound or bell ringing). Many barking styles appear to reflect uncertainty and conflict of incompatible emotional and behavioral tendencies evoked by the approach of an unfamiliar person. Conflictive barking activity may allow the dog to hold ground, secure the stranger's attention, and keep the intruder at a safe distance, but without necessarily wanting to drive them away. As such, the barking response may delay social decisions about engagement, disengagement, or confrontation long enough to assess the relative safety and significance of the situation. Still other dogs will bark and continue to threaten persons with whom they are familiar but who are viewed as outsiders. Such dogs may tolerate a guest if the guest remains in the yard (the familiar space) but threaten a guest who comes in the house (the familial space). Finally, not all dogs bark to give alarm or threaten people, and many will bark just because they are intoxicated with the excitement of someone visiting the house. In fact, most barking by dogs in response to visitors to the home appears to be related to nonspecific excitement—not aggressive intent.

Variables Affecting Extrafamilial Aggression

Under the influence of confinement and restraint (e.g., when inside a car, crated, or chained) territory-like aggression may be invigorated (see *Variables Influencing Territorial Aggression* in Volume 2, Chapter 7). Children appear to be at an increased risk of serious attacks by chained dogs or by dogs that have broken free of chain restraint. Although keeping a dog continuously on a chain appears to exert a potent agitating effect—as Shaw (1906) says, "The chain makes a dog savage"—the results of a study performed by Le Boeuf (1967) in which dogs were periodically staked out and exposed to the approach of free-moving male and female dogs do not support the notion that chaining per se makes dogs more aggressive. Occasional and brief tethering outdoors is unlikely to produce adverse welfare effects or alter aggression levels, but the quality-of-life degradation, agitation, frustration, lack of gratifying social contact, and entrapment associated with excessive and routine chaining and penning of dogs outdoors may significantly increase a dog's aggressive propensities. A major source of increased risk associated with chaining is simply the result of increasing the public's exposure to an aggressive dog. Whereas a fence provides a protective, albeit imperfect, barrier, a dog on a chain is much more accessible to the approach of a stranger or an innocent child. Excessive confinement of a dog appears to reflect a failure of the family to integrate the dog effectively into the home.

Based on opinions that continuous tethering can be inhumane, the U.S. Department of Agriculture (USDA) has banned the practice of tethering in facilities that fall under its jurisdiction (Animal and Plant Health Inspection Service, USDA, 1997). To test the hypothesis that penning might be better for the dog than tethering, Yeon and colleagues (2001) performed a study that evaluated the behavioral effects of tethering and penning on Alaskan sled dogs. The study failed to show a significant welfare advantage from penning in comparison to tethering: "Our findings provide no evidence that tethering was any more or less detrimental to dog welfare than being

housed in pens (as recommended by the USDA)" (2001:268–269). These preliminary findings appear to suggest that both forms of confinement can be equally problematic when used to restrain dogs continuously. The report appears to raise significant welfare issues about the use of continuous pen confinement, as well as continuous tethering. Consequently, if tethering and penning are equally stressful, then alternative means of laboratory housing may need to be explored and recommendations made based on scientific findings rather than good intentions. Ultimately, however, as the result of the dog's special needs for human companionship, its highly developed social cognitive abilities, and its adaptation to domestic life, there may not be any practical way to house dogs under laboratory conditions that one can truly call *humane*, or honestly say that it serves a dog's best interests and welfare, without at the same time appearing painfully ignorant of the dog's nature and devoid of anything approaching sincerity with respect to laudable aspirations pertaining to animal welfare.

Social facilitation and inhibition appear to exert a significant effect on extrafamilial aggression. Two dogs aroused by the same provocative target may stimulate aggressive arousal in each other that exceeds what either of them would do if alone. The facilitative effect in such cases is often so strong that a third entity appears to emerge from the two, an effect reminiscent of the ferocious three-headed Cerberus, the mythical guard dog of Hades (Figure 8.2). The connection suggests a nice term for the social facilitation of extrafamilial aggression toward unfamiliar outsiders: the *Cerberus effect*. Dogs may also exert a significant, but less recognized, inhibitory effect on the barking behavior of other dogs. Scott (1983), for example, described an interesting situation illustrating the effects of social inhibition on territory-like behavior. He observed that when shelties and beagles were housed together, the shelties consistently became controlling over the beagles. Both shelties and beagles exhibit a very strong tendency to bark at strangers, but when reared together the more controlling shelties kept the yielding beagles from barking, resulting in "barkless beagles" (8). In other cases, social facilitation and inhibition might interact dynamically in the context of complex activities, such as predatory behavior. Dogs that might not otherwise be tempted into chasing or harming another animal may be caused to engage in such activity by the example of an aggressive model. For example, Christiansen and colleagues (2001) found that when a dog that did not chase sheep was paired up with a dog that did, the nonchaser invariably chased sheep. However, they also found that the presence of the nonchasing companion had an inhibitory effect on the severity of the attacks made by dogs that chase sheep when alone.

Conflicts and Rituals Toward Novel Social Stimuli

Ritualized activities such as barking, lateral pacing, and turning about often develop in association with the conflictive arousal and opponent behavioral dynamics evoked by the presence of an unfamiliar person or dog. The bark and motor responses may help modulate arousal (sympathovagal tone) and prevent a dog from reacting to the intruder prematurely or inappropriately. Instead of simply attacking, retreating, exploiting, or accepting the intruder's presence, the barking ritual may serve a number of adaptive coping functions by enabling the dog to hold ground, to *take time* to evaluate the situation, or to *kill time* to let the situation develop and become better defined before deciding what to do next. The ritual activates and maintains a state of general excitement and readiness conducive to several possible courses of action: emergency (flight-fight), acceptance (flirt-forbear), or exploitation. Whereas unstable and reactive dogs are prone to confront intruders or run away in accord with a negative expectancy bias toward unfamiliar persons, dogs operating under an adaptive coping style are more likely to respond to intruders in accord with a positive expectancy bias and response toward novelty (see *Expectancy Bias* in Volume 2, Chapter 3). Impulsive dogs operating under the influence of behavioral disinhibition may bark wildly and then exploit a visitor for anything they can get. Dogs operating under a reactive coping style tend to perceive social

FIG. 8.2. Territorial aggression can represent a serious threat of injury, especially when occurring under the influence of offensive incentives. This dog became aggressively aroused when approached and undeterred by the presentation of food, which he would eat and immediately return, threaten, and bite at the fence. As a puppy, he was removed from its litter shortly after birth and raised in a shelter environment until he was 2 months old, when he was adopted. The dog was returned to the shelter at 8 months after attacking and pinning his owner to the ground. The owner received several bites to her hands and arms. Over the course of the 2 years in the shelter, the dog became progressively reactive and could not be safely approached by anyone, despite efforts to socialize and train him.

novelty and sudden change as intrinsically threatening and respond to outsiders with preemptive preparations for social confrontation or disengagement via the activation of the flight-fight system.

Dogs showing a reactive coping style operate under the precarious influence of an unstable equilibrium between attacking and avoiding visitors that may rapidly and precipitously shift in the direction of one extreme or the other. Although such dogs may exhibit relatively stable behavior while under the influence of familiar circumstances and optimal levels of arousal and stimulation, they can rapidly transition into a fearful, irritable, or confrontational orientation when responding to an unfamiliar person perceived as posing a threat or challenge. Such dogs seem to jump from a "Who's that?" or "What's that?" orienting phase (e.g., sound of a doorbell or person standing up) to an impulsive reactive phase. Cognizant of the potential danger, the owner may attempt to comfort and reassure the dog in hopes of facilitating more friendly behavior or at least to prevent the dog from launching into an attack or retreating from the situation. However, like a double-edged dagger held upright on its tip by the support of a finger keeping it steady, the unstable equilibrium shown by such dogs can be immediately lost as the owner withdraws support or lets down his or her guard. The inflexible pattern of repetitive aggressive threats that such dogs sometimes show toward visitors holds more in common with a compulsion than an adaptive behavior operating in accordance with functional prediction-control expectancies and calibrated emotional establishing operations. To refer to such behavior as protective or territorial is rather misleading, especially since the behavior occurs independently of any apparent threat to family or property. In most cases, such aggressive behavior is probably better understood as an autoprotective response to the uncertainty evoked by the unexpected appearance and approach of an unfamiliar person. Conversely, an adaptive dog's positive orientation toward uncertainty via the formation of viable expectancies and competence may facilitate more friendly social engagement. For such dogs, the alarm-barking ritual gives way to a

control incentive urging the dog forward to seek reward by initiating social exchanges with the visitor. In an important sense, adaptive dogs are oriented toward the conditional significance of events in order to optimize reward opportunities and avoid punishment (i.e., loss of comfort or safety), whereas reactive dogs are more concerned with the here-and-now unconditional significance of appetitive and aversive events.

The unexpected appearance of the stranger or outsider sets the stage for interactive scenes between the dog and visitor that take place under the influence of a reactive bias of uncertainty and suspicion. Dogs showing deficiencies in their ability to habituate or cope with social novelty and strangeness often show a highly reactive orienting response that may become progressively vigilant and dedicated to a rigid watchdog script. Affected dogs appear to combine a sustained suspicion or suspense toward strangers, indicating an inability to habituate and to activate the social engagement system (SES), which may remain in a state of phasic retraction so long as the dog perceives the situation or the person as unsafe (i.e., strange). Without sufficient social attraction to offset repulsion toward visitors, the dog may take food from them but not integrate social relations incompatible with aggression toward them; in fact, some such dogs, especially those expressing trait aggression, may become increasingly dangerous as their fear is reduced by food. Just as prey animals can eat while remaining vigilant for predators, dogs in a persistent autoprotective mode will take food but remain ever vigilant and ready to launch an attack against any unexpected changes or movements perceived as a threat. The person giving food remains an outsider and continues to be perceived as a significant threat. As a result, even though the dog's level of fear may be reduced, the SES may remain off-line, so to speak, and prevent the integration of friendly relations. Many of the foregoing characteristics point to the possible involvement of vagal deregulation, whereby the detection of social novelty and unexpected change mediates heart-rate changes conducive to a rigidly defensive orientation that impair a dog's ability to process benign social events and respond with appropriately regulated behavior. Instead of responding with heart-rate deceleration when orienting and exploring a visitor, reactive dogs may fail to fully habituate but instead maintain a state of attentional vigilance and readiness characteristic of sympathetic arousal. Such dogs may have diminished HRV, reflecting reduced vagal tone and predisposing them to overreact to the slightest change in a visitor's behavior after they have apparently calmed down.

WATCHDOG BEHAVIOR

Aggression always occurs within a sociospatial frame of reference, but the reasons dogs show aggression are not always explicitly or obviously motivated by alloprotective or territorial incentives, although such incentives appear to exist in certain dogs. In many cases, aggression appears to be motivated by autoprotective incentives or merely represents an impulsive reaction to social novelty or sudden change without reference to redeeming territorial or social purposes; that is, the mere uncertainty presented by a stranger may trigger a preemptive wariness or evoke aggression in a predisposed dog. Alarm barking and threat barking are normal and useful when expressed appropriately, but under the influence of inadequate socialization or improper training, social novelty or unexpected change may generate a catastrophic shift in autoprotective arousal that sets off reactive adjustments that are impulsive and difficult to control.

Alarm at Uncertainty: Discriminating the Familiar and the Unfamiliar

The tendency of dogs to become wary and alarmed by the approach of strangers prompted Heraclitus to remark, "Dogs bark at the man they do not know" (Nahm, 1964:75). This rather prosaic observation, as characteristic of the Dark One of Ephesus, probably held a deeper significance for the cryptic philosopher than the obviously false notion that dogs bark only at people they do not know (see *Barking, Motor Displays, and Autonomic Arousal*). Plato also considers the

significance of knowing and not knowing as it relates to watchdog behavior in *The Republic* (Jowett, 1941). The subject is raised in the context of a philosophical discussion pertaining to the relationship between beliefs and actions. Socrates held that effective action depends on one's ability to discriminate between what is known and what is not known and then to act in accord with the former and to avoid the latter. In a dialogue between Socrates and Glaucon, the philosopher notes that these discriminative abilities are traits shown by a good watchdog:

> Many animals, I replied, furnish examples of them; our friend the dog is a very good one: you know that well-bred dogs are perfectly gentle to their familiars and acquaintances, and the reverse to strangers.
>
> Yes, I know.
>
> Then there is nothing impossible or out of the order of nature in our finding a guardian who has a similar combination of qualities?
>
> Certainly not.
>
> Would not he who is fitted to be a guardian, besides the spirited nature, need to have the qualities of a philosopher?
>
> I do not apprehend your meaning.
>
> The trait of which I am speaking, I replied, may be also seen in the dog, and is remarkable in the animal.
>
> What trait?
>
> Why, a dog, whenever he sees a stranger, is angry; when an acquaintance, he welcomes him, although the one has never done him any harm, nor the other any good. Did this never strike you as curious?
>
> The matter never struck me before; but I quite recognize the truth of your remark.
>
> And surely this instinct of the dog is very charming; your dog is a true philosopher.
>
> Why?
>
> Why, because he distinguishes the face of a friend and of an enemy only by the criterion of knowing and not knowing. And must not an animal be a lover of learning who determines what he likes and dislikes by the test of knowledge and ignorance. (375a–e)

According to the Socratic ideal, a good watchdog is the result of selective breeding for the mental and physical abilities that enable it to discriminate friend from foe and to act effectively upon that knowledge, traits that apply equally well to the selection and training of guardian rulers of the city-state. A watchdog must be vigilant for intruders and bold in its readiness to confront them. Such dogs must possess a physical size, strength, and fleetness sufficient to chase and subdue an intruder, while always treating those familiar to them with affection and gentleness. The tendency of dogs to show friendliness toward familiar people but hostility toward strangers was interpreted by Socrates as evidence of rational conduct. The dog's ability to discriminate friend from foe on the basis of relative familiarity and unfamiliarity, and then to act in accord with such knowledge, won the philosopher's admiration. The Socratic oath "by the dog of Egypt" is an apparent tribute to the dog's sagacity and ability to make fine social judgments based on the discrimination of what is known (recognized) and unknown (uncertain) about a person. The reference to Anubis, the dog god of Egypt, may allude to a canine power to search a person's heart and discern secret intent. Just as the judgment of Anubis served to grant or deny a deceased person access to the Fields of Peace in Egyptian mythology, the dog appears to play at least a symbolic role in determining whether a visitor is admitted into the home or turned away at the threshold.

Although it is certainly true in everyday life, as Heraclitus observed, that dogs often bark at strangers, some do not bark at strangers, and still others bark at persons they know well or just bark because they are excited by the approach of someone that they love. Further, although dogs are usually friendly toward people they know, many are also exceedingly outgoing and obtrusive toward people they do not know—the antithesis of Socrates's watchdog ideal. Finally, mere familiarity with a dog does not ensure friendliness, nor does it necessarily constrain the dog's animus. In fact, some dogs may even attack a familiar person without any provocation, perhaps only because the person intruded upon a forbidden social space or engaged in exchanges reserved for affiliated others. Nevertheless, the basic pattern described by Socrates appears to be generally faithful to the behavior exhibited by a great many dogs showing extrafamilial aggression:

whereas familiar people are recognized as safe and treated in a friendly way, unfamiliar people are regarded as a potential threat and treated with alarm and suspicion, even though the latter may offer the dog food and other rewards to reassure it of a friendly intent. Aggression targeting unfamiliar persons may occur with significant conflict and barking, or it may be triggered with no apparent conflict or barking. In such cases, as soon as the dog spots the intruder, it may fiercely rush the target and attempt to bite. Still other dogs may attack visitors only after appearing to have slowly accepted them. Dogs showing such behavior require lifelong supervision and appropriate physical restraint to avoid future attacks when exposed to unfamiliar persons or familiar outsiders.

Flexible versus Rigid Watchdog Scripts

Normally, social novelty and sudden change (e.g., unfamiliar persons in association with the ringing of a doorbell) evoke excitement and approach-avoidance conflict causing dogs to bark, followed by friendly resolution and approach, social investigation, and the initiation of reward-seeking behavior toward visitors. This familiar pattern of friendly proactive and prosocial behavior is disrupted in extrafamilial aggressors. Instead of merely hesitating and barking (ritualizing) before approaching and initiating prosocial introductory and exploratory behavior, the aggressor shifts instantly from alarm arousal evoked by sudden change or social novelty to a confrontational orientation, transforming a visitor into an object for the discharge of aggressive tensions and threats. Whereas most reactive dogs appear to warm up slowly to visitors (flexible watchdog script) and accept their approach and contact, other dogs (rigid watchdog script) may resist such accommodation and remain persistently on guard, even after repeated uneventful visits. Some of these dogs may appear to warm up to a visitor but then suddenly become aggressively aroused and threatening toward the visitor. The tendency of dogs that show a flexible or *habituating* watchdog script to warm up slowly to visitors and to show tolerance or initiate friendly behavior is consistent with the social novelty hypothesis. Such dogs rapidly and competently habituate to the novelty of an unfamiliar person and show an ability to initiate or reciprocate friendly social contact based on expectancies derived from the behavior of the visitor. The appearance of friendly tolerance can be deceptive, however, especially with dogs showing a rigid or *nonhabituating* watchdog script. Such dogs not only preemptively react to the strangeness of a visitor but also appear to discriminate between persons perceived as belonging to the household (insiders) and all others not belonging to the household (outsiders). Even as a dog becomes familiar with the visitor, it may refuse to integrate friendly relations with the outsider (see *Variables Affecting Extrafamilial Aggression*). In many cases, defensive and offensive components appear to conjugate in peculiar ways in such aggressors, whereby dogs operating under the influence of conflict and a rigid watchdog script may readily accept food and even tolerate petting from visitors but then shift back into an aggressive mode and threaten or bite them as they stop or attack from behind as a guest gets up to leave the house. Such aggressive behavior in response to an upturn of activity and sudden change appear to implicate a sympathovagal mechanism. The tendency of such dogs to threaten or bite visitors as they get up, when they approach the owner, or when they prepare to leave the house may be related to rapid shifts in autonomic arousal. Special precautions need to be taken and maintained until such aggressors show unambiguous signs of friendly acceptance toward the visitor.

Most dog owners appear to welcome a moderate amount of alarm barking and household protection as an added benefit of dog ownership. In some cases, wariness toward strangers is not only appreciated and encouraged, but the dog may gain a special status as the family's protector as the result of its territorial prowess. Unfortunately, aggressive propensities in the absence of proper training are often misdirected and turned haphazardly against family members or innocent persons visiting the home rather than against criminals (see *Incidence and Targets of*

Aggression in Volume 2, Chapter 6). Children are the most frequent targets of such bites, followed by passing adults, neighbors, and innocent visitors to the home (Blackshaw, 1991). Despite the dangers represented by untrained dogs, with appropriate training and socialization, the rigid watchdog type can be of tremendous value for personal protection and working purposes. In the hands of unskilled owners or busy households, though, such dogs represent a significant risk. In contrast to a reactive aggressor, a properly trained protection dog is a marvel of behavioral control and interspecies cooperation. As the result of effective training, the dog's aggressive impulses are systematically augmented and educated while inhibitory control is enhanced. Interestingly, dogs that have been skillfully trained in protection work are rarely presented with problems related to aggression. From a training theory perspective, integrating the aggressive impulse into a functional activity organized in accord with adaptive control expectancies and calibrated establishing operations represents a potentially valuable way to convert the conflictive or reactive impulse to threaten or attack into a proactive pattern of highly controlled protection behaviors. Such training appears to enable dogs to autoregulate impulses that previously operated under loose executive control. Systematic obedience and protection training shapes and integrates aggressive impulse into a proactive pattern of alert, threat, attack/attack-stop, bite/bite-release, guard, and denouement sequences. As an adjunct strategy, the goal of such training is not to make an extrafamilial aggressor into a protection dog, but to incorporate protection-training methodologies as a means to convert impulsive and reactive aggression into a more proactive form, making it responsive to contingent outcomes and inhibitory control. By bringing the aggressive impulse under instrumental control, an adaptive platform for subsequent behavior-therapy efforts may be established.

Although the combination of obedience and protection training may be a reasonable approach in certain cases, in the author's experience, the sort of commitment, dog sense, and experience needed to make such training a success is rarely found in average households. Further, improper handling and incompetent protection training may only serve to make a dog more dangerous and difficult to handle. Many legal and practical factors need to be carefully considered before recommending such a strategy, but with highly dedicated and responsible dog owners such training might be explored as an option in the treatment of dogs living under the right set of circumstances that justify the risks involved. Select dogs and owners that might benefit from such training are most likely to receive responsible guidance and competent instruction from trainers working in association with established schutzhund organizations.

Attention and Autonomic Regulation

Attentional processing of significant events is divided into four steps—target arc, orienting, sustained attention, and attention termination—that simultaneously coordinate autonomic and cognitive adjustments and the expression of changes to cardiovascular activity. In addition, attentional behavior is strongly influenced by the autonomic effects of interference (distracter stimuli) and interruption (diverter or disrupter stimuli). The detection of the target stimulus produces a rapid parasympathetic effect that is observable within the first beat after the stimulus is detected (Berntson et al., 1992) roughly corresponding to the temporal relation between the flinch-alert response produced by the S1 (squeak) and S2 (click) in target-arc training (TAT). In contrast to the rapid parasympathetic changes, sympathetic effects on the canine heart are more sluggish and may take 2 to 3 seconds or longer to develop (Berntson et al., 1992). The sympathetic phase corresponds to the flick, treat, and pet sequence in TAT (see *Attention and Play Therapy*). These findings indicate that autonomic processing is temporally partitioned in a way that favors the antecedent activation of parasympathetic circuits in advance of sympathetic ones in the process of organizing a controlled response to unexpected events producing surprise or star-

tle. In addition to autonomic partitioning, a dog's response to significant attractive or aversive events evoking surprise or startle appears to be moderated by the coincidence of nonevocative stimuli that occur in a close forward contiguity with the evocative event. In the case of startling stimuli, these antecedent neutral stimuli serve to attenuate fear responses evoked by the unexpected startle, an effect referred to as *prepulse inhibition* (see *Interrupting Behavior* in Chapter 1). As a result of the buffering effect on withdrawal behavior mediated by the antecedent stimulus, the previously neutral antecedent stimulus may enable a dog to cope more effectively with such sources of startle in the future, appearing to play an important role in the integration of passive modal strategies and proactive avoidance behavior. One might imagine that a similar effect is produced by antecedent stimuli linked with attractive stimuli producing surprise, but instead of reducing arousal associated with surprise, as in the case of startle, such antecedent stimuli linked preattentively with surprise may serve to amplify seeking incentives in association with the mobilization of active modal strategies.

These behavior-modulating capacities are reflected in preattentive bias and searching behavior, causing the dog to show a preferential alertness or vigilance for the detection of antecedent stimuli evocative of excitement or apprehension, thereby facilitating and setting the stage for an orienting or defensive response. Such preattentive biases are probably preferentially linked with neutral stimuli via a filtering process that excludes stimuli that are already associatively valenced with attractive or aversive bias, thereby preventing the cross-association of opposing arousal states. Such a filtering process would be necessary to guard against the confusion that would flow from an antecedent stimulus that evoked both excitement and apprehension at once or evoked inappropriately high levels of excitement or apprehension toward an event or stimulus warranting only minor attention, causing the dog to search inappropriately, unnecessarily, or persistently for significant events and impairing its ability to orient or engage selective attention capacities effectively.

These rapid preattentive gating and information-handling processes serve to invigorate attentional systems and tune autonomic motor systems for impending action. The adaptive changes configured in preattentive processing appear to profoundly influence a dog's capacity to hesitate (to "wait and see") and to selectively orient and attend to social and environmental stimuli and to extract significance from their occurrence for the optimization of prediction-control expectancies. In less time than it takes for the heart to beat, the eye to blink, or the puppy to yelp, autonomic circuits integrate a critical shift in arousal while mediating adaptive adjustments to environmental change. In contrast to the rapid deceleration effects of automatic targeting responses, the orienting response is associated with a slower inhibitory or excitatory effect on heart rate, reflecting the interaction of parasympathetic (vagal) and sympathetic influences on canine cardiovascular activity (Billman and Dujardin, 1990; Little et al., 1999). The orienting response is associated with a discrimination process, resulting in the differentiation of stimuli warranting immediate attention from those that do not, with the latter stimuli undergoing a process of habituation. Stimuli evoking attention activate cortical processing for evaluating an event's prediction-control significance and to stimulate an appropriate level of emotional arousal while selecting a measured and appropriate response. During periods of sustained attention, autonomic changes result in the stimulation, inhibition, and disinhibition of cardiovascular activity via gross and subtle changes mediated by sympathetic and parasympathetic divisions of the autonomic nervous system (ANS) on vagal tone. The various effects of cognitive and emotional processing on autonomic arousal and heart activity may index attentional effort and emotional establishing operations while matching arousal to behavioral needs. Among humans, sustained attention has a profound influence on vagal tone, which Porges (1992) has compared to partial atropine blockade, resulting in a phasic reduction in HRV. He found that children with attention and impulse-control deficits show disturbances in their ability to appropriately

adjust vagal tone while engaged in activities requiring sustained attention. In comparison to children not exhibiting ADHD, children diagnosed with ADHD exhibit increased phasic HRV, a difference that is removed by medication with the psychostimulant methylphenidate. The HRV during sustained attention shown by children with ADHD appears to reflect reduced mental effort in comparison to controls without ADHD, implicating an executive frontal role in the phasic modulation of vagal tone during sustained attention (Borger et al., 1999).

Attentive and preattentive functions play a profoundly influential role in the organization of adaptive and reactive coping styles. The critical interface between the external and internal environment is mediated by attention and the modulatory effects it has on autonomic arousal. External and internal environmental conditions exert a number of limitations on attentional resources that may lead to disturbances affecting a dog's impulse control, mood, and ability to cope with stress. According to cynopraxic theory, the aversive states of arousal associated with anxiety, frustration, anger, boredom, and depression are the acute (phasic) and chronic (tonic) correlates of attentional disturbances and autonomic deregulation impairing a dog's ability to achieve adaptive attunement and harmony via behavioral initiative. The quality of life (QOL) index is broadly correlated with the relative social and environmental order and variety, with extremes in either direction resulting in attentional disengagement, autonomic deregulation, and increased impulsivity resulting from anxiety (harm avoidance) and boredom (lack of stimulation or novelty seeking). Cynopraxic theory postulates that anxiety and boredom are the result of environmental conditions that lack sufficient order or variety to support attentional engagement. Accordingly, anxiety is the autonomic correlate of social and environmental conditions that lack sufficient order (consistency and predictability) to *support* attentional engagement, whereas boredom is the autonomic correlate of environmental conditions that lack sufficient variety (novelty and uncertainty) to *sustain* attentional engagement. In both cases, attentional disengagement results in reduced impulse control and behavioral changes tending toward depressive or compulsive disorder.

In addition to external social and environmental influences, internal drive conditions originating in overactive subcortical networks may overstrain attentional functions, causing them to develop an opposite pattern of incapacitation associated with an inability to flexibly disengage attention, to habituate to irrelevant stimuli, or to shift attentional focus selectively in accord with prediction-control expectancies. Reactive dogs appear to approach the environment in a rigid and one-dimensional way, showing a high degree of vigilance and readiness to act, depending on preattentive biases (positive or negative), preemptive arousal, and the behavioral system involved. Reactive dogs express four general patterns of hyperexcitability in association with an *inability to disengage* attentional processing: excessive seeking, exploiting, avoiding, and fighting. In contrast to reactive dogs, impulsive dogs are saddled with an opposite attentional burden resulting from social interaction that lacks sufficient consistency or clarity to form reliable prediction-control expectancies and calibrated establishing operations. Instead of being unable to disengage attention and relax, impulsive dogs appear to be motivationally disengaged from social stimuli. Operating under the influence of social ambivalence and loner/dispersive tensions, impulsive dogs may automatically disengage attentional resources, perhaps as a measure to protect cognitive processing from the adverse influence of information inadequate or inimical to the formation of predictive correlations. Dogs that respond to social proximity and contact with motivated efforts to disengage attention tread a perilous tightrope, because withdrawal of attentional resources is anxiogenic and tantamount to relinquishing control over impulse. The reactive or intentional disengagement of attention is hypothesized to result in blunted prefrontal activity and the deregulation of parasympathetic tone, a state of instability that is further amplified and complicated by the loss of social attraction. The retraction of the SES incurs the loss of emotional regulation and

vagal stability afforded by attunement with attachment objects, as well as mediating anger—the motivational state mediating social repulsion. As the result of the social and attentional disengagement, a dog may become increasingly vulnerable toward ambiguous or conflictive social signals, causing the momentary arrest of parasympathetic outflow and promoting a preparatory state of catastrophic arousal. The sympathovagal imbalance associated with the disengagement of attentional and social resources not only mediates generalized anxiety, the lack of autonomic stability exhibited by such dogs appears to contribute to increased moodiness, impulsivity, and changes in general activity levels.

Dogs with flexible attention skills can form and test prediction-control expectancies and adjust their behavior accordingly, thereby enabling them to anticipate events and to prepare emotionally in advance to behave in ways that are most likely to succeed. In contrast to the rigid adjustment styles of reactive and impulsive dogs, dogs expressing an adaptive coping style can rapidly shift expectancies and emotional arousal in order to keep pace with changing circumstances and, in doing so, optimize their ability to respond competently to significant events.

Play and Autonomic Attunement

The propensity to play is not equal among dogs. Dogs evidencing emotional and behavioral disturbances associated with anxiety, fear, and anger often show significant impairments in their abilities to sustain playful interaction with other dogs and people. Reduced exploratory behavior and playfulness may impair a dog's ability to cope adaptively with unfamiliar or uncertain situations, as well as diminish its ability to initiate or reciprocate competent exchanges needed for social engagement and integration of secure attachments with family members. A reduced alertness for signals of reward is characteristic of a reactive coping style, perhaps, by default, forcing such dogs to rely on signals of punishment and unconditioned sources of gratification. The emotional states associated with a reactive coping style (anxiety, anger, irritability, intolerance, and withdrawal) may simply reflect the mood changes that occur when a dog cannot effectively process and experience the rewards necessary to play and to actively learn.

The ability to play is probably organized at an early age. Among wolves, play fighting emerges as a prominent mode of social interaction in advance of fighting in earnest and the establishment of sibling hierarchy relations. In contrast, less sociable canids (e.g., coyotes, jackals, and red foxes) show more aggressive behavior and less play as infants than do wolves and dogs (Bekoff, 1977). Individual and breed differences affect a dog's propensity to fight. For example, Frank and Frank (1982) found that malamute puppies show "unrestrained fighting" (513) starting at week 2 and do not exhibit play fighting until weeks 4 to 5. Wolf pups exhibit an opposite pattern, with play fighting appearing during week 2, followed by a brief period of serious fighting between weeks 4 and 6. The malamute's adult predilection for intermale fighting may be attributable to permanent epigenetic changes affecting sympathovagal tone that stem from the ontogenetic timing and order of agonistic contests in relation to the emergence of play. Developmentally antecedent play may integrate an autonomic tone that enables dogs to cope less reactively with agonistic exchanges later on, whereas developmentally antecedent fighting or the absence of coemergent play may adversely sensitize and permanently bias dogs with a more reactive orientation toward social agonism. Highly sociable dog breeds appear to show more playfulness and less overt fighting than breeds prone to excessive interspecific aggression in adulthood. As a result, some dog breeds appear to be far more aggressive than wolves, whereas others are much less aggressive, reflecting breed differences and the effects of selective breeding pressures on aggressive propensities (Scott and Fuller, 1965).

Lund and Vestergaard (1998) found that the levels of play versus social agonism shown by dogs between weeks 6 and 8 is negatively correlated with the levels of play and social

agonism present at week 3 and weeks 3 to 4, respectively. In other words, puppies that played less at 3 weeks of age tended to play more later on, whereas puppies that fought more during weeks 3 to 4 fought less later on. Conversely, puppies that play less early on play more later on, whereas puppies that fight less early on fight more later on. These changes are attributed to compensatory rebound effects, but may just as likely reflect developmental processes and neurodevelopmental shifts mediating the expression of different temperament types. The developmental timing of play fighting and social agonism appears to exert a lasting influence on sympathovagal tone. A period of parasympathetic dominance emerging at around week 3 is followed by a brief sympathetic rebound between weeks 5 and 7, gradually moving toward progressive autonomic equilibrium through week 16 [see *Primary Socialization (3 to 5 Weeks)* in Volume 1, Chapter 2]. The autonomic fluctuations and behavioral rebound effects during these early weeks of development are reflected in significant heart-rate changes (Scott and Fuller, 1965), which are strongly correlated with changing emotional propensities that differentially enhance social attraction and play (parasympathetic dominance) or facilitate emergent social agonism and fear (sympathetic dominance). The physiological integration of mechanisms that facilitate neonatal thermoregulation may foreshadow the organization of regulatory systems dedicated to the control of sympathovagal arousal and flight-fight adjustments, suggesting the need for studies to track and correlate temperature variations with autonomic changes occurring during this period of development. Temperature changes in response to social stressors may provide revealing information and help to detect sympathovagal disturbances at an early age.

An improved ability to regulate sympathetic arousal is hypothesized to emerge during this integrative period of neurodevelopment, together with emergent social skills facilitating competent social interaction, engagement and bonding, disengagement and separation, and confrontation and defense. Accordingly, social attraction and the timing of play and fighting during these early weeks may exert lasting effects on the functional integration and relative equilibrium or disequilibrium of autonomic activity, thereby predisposing a dog at an early age toward sympathovagal balance or imbalance and the integration of an adaptive (proactive) or a reactive coping style in adulthood. Tendencies toward a reactive coping style may develop in association with autonomic imbalance resulting in either potentiation (allostatic hyperdrive) or blunting (allostatic hypodrive) of the HPA system, whereas an adaptive coping style appears to help integrate an adaptogenic response to stressors (allostatic normodrive). Finally, the energetic tactile stimulation associated with social play may contribute to the activation of an oxytocin-mediated antistress system. The canine flirt-and-forbear system is hypothesized to enable dogs to cope more effectively with stressors associated with social ambivalence and antagonism. Conversely, serious fighting between littermates may sensitize the AVP/CRF flight-or-fight system, perhaps reducing the ability of such dogs to form friendly and playful relations as adults. Competent social skills and trust appear to develop in the context of play, perhaps via adaptive parasympathetic attunement and vagal control developing in association with play activities.

Evidence supporting the hypothesis that autonomic tone is integrated at an early age and that it might exert a persistent influence predisposing dogs to integrate a reactive or adaptive coping style has been reported by Clark (1994), who studied the cardiac acceleration and deceleration responses of puppies exposed to brief restraint, elevation stress, and pain or startle elicited by tactile, auditory, and visual stimuli. Baseline heart-rate measures were obtained and compared with heart-rate recovery patterns. Puppies that showed emotionally reactive (anxious) temperaments, as indicated by owner reports and temperament tests, tended to return to baseline heart rates more slowly than puppies that exhibited less emotionally reactive temperaments. The study found breed and individual differences linking lengthier heart-rate recovery periods with heightened emotional reactivity, whereas

socially confident dogs tended to show briefer heart-rate recovery periods consistent with competent sympathovagal tone. These findings suggest that heart-rate and poststimulation recovery patterns may offer predictive or diagnostic markers for identifying puppies prone to integrate reactive coping styles, recommending the routine collection of heart-rate data as part of puppy testing.

Play in the absence of a principle of fairness and empathy degrades into cruelty and exploitation via a composite motivational influence of lust, greed, and power when unilateral advantages are sought without concern for the loss or pain suffered by the coplayer. The excitement of taking an advantage at the expense of the play partner appears to be an important motivational aspect of exploitative play, perhaps explaining why play sometimes slips into serious competition and overt fighting. A serious form of impulsive aggression exemplifies this tendency that may be shown by certain outgoing dogs bred for enhanced fighting propensities and expressing intrusive exploitative and power-dominance motivations toward unfamiliar persons. Up until the flash point, the dog may wear a "happy clown" face and only show evidence of a growing threat by an unmistakable attitude shift and increasing roughness, often matched with a deceptively charming "pretty boy" look and constant eye contact, seeming to lure the player in for more fun. Should the handler attempt to shift the play toward an advantage or abruptly stop, the intensity of the exchanges may torque up and suddenly turn into an all-out attack. The foregoing is one example of many types of situations where pseudoludic interaction may set the stage for aggression. Usually, play with such dogs is held off until a foundation of familiarity, cooperation, and trust is established. When play is initiated with a potentially aggressive dog, keeping the dog on tie-out and directing its play energy into an object is a useful precaution. Learning to trust ones "gut" is critical for avoiding dangerous situations such as the one just described. Knowing when to play or not is something that a trainer learns only with experience, close calls, and sometimes the wisdom born of hard knocks.

ATTENTION AND PLAY THERAPY

Dogs functioning under a reactive coping style appear to harbor negative biases that predispose them to process social uncertainty and sudden change as a threat or challenge rather than a potential source of reward. Affected dogs may be unable to habituate to the perceived threat of an outsider or may do so very slowly and only after many safe encounters. Reactive dogs of this type pose a significant risk of snapping or biting strangers or familiar outsiders who approach or attempt to interact with them too soon in the social familiarization process or approach them in unexpected ways. Such dogs may be particularly dangerous in unfamiliar situations perceived as unsafe and previously associated with loss, discomfort, or risk. Most behavior problems are shaped while a dog copes with aversive affects stemming from a history of interactive conflict and a failure to produce reward or to avoid punishment (activity failure). The Stoic philosopher, Epictetus (Internet Classics Archive, 2000), speaks to these distressful affects in his *Discourses*: "An affect is produced in no other way than by a failing to obtain that which a man desires or a falling into that which a man would wish to avoid … and by these causes we are unable even to listen to the precepts of reason" (3.2). Cynopraxic training and therapy efforts are organized with the goal of reducing the distressing affects of *failing and falling* and the consequent reactive adjustments to loss and risk by educating, in the words of Epictetus, the "faculty of pursuing an object and avoiding it, and the faculty of desire and aversion, and, in a word, the faculty of using the appearances of things" (1.1). Learning successfully to predict and control the environment serves to integrate an adaptive coping style, competence, playfulness, a bias of safety, and spontaneity, that is, the ability to autoinitiate prosocial behavior conducive to interactive harmony.

Attention Disturbances, Dissociation, and Orienting/Target-arc Training

The theory underlying the efficacy of orienting/TAT supposes that preattentive arousal

and submerged attentional functions mediating reactive adjustments are gradually linked and integrated into a network of cortical prediction-control expectancies and calibrated establishing operations in the process of mediating functional attention and impulse control. The process appears to reboot executive functions while enlivening the SES. A critical factor in this process is training the attention to orient selectively toward the flow of events with the purpose of detecting and appraising the significance of prediction error occurring in the context of purposeful behavioral projects and ventures, and appropriately adjusting behavioral output to accord with a preference for surprise (positive prediction error) and an aversion for disappointment (negative prediction error). Essentially, prediction error occurs when an anticipated outcome is better than expected or worse than expected, thereby mobilizing adaptive modal strategies aimed at producing more surprise (e.g., increased searching and exploration) while avoiding disappointment (e.g., hesitating and waiting). The systematic juxtaposing of a standard expectancy against appetitive events that variably result in verification or positive (surprise) and negative (disappointment) prediction error serves to enliven cortical learning functions and facilitate the organization of prediction-control expectancies and calibrated establishing operations (control modules). Prediction error results in hedonic as well as cognitive and behavior changes compatible with the optimization of activity success and the integration of an adaptive coping style.

Orienting/TAT appears to facilitate the integration of a selective-attention interface that enables dogs to sort out relevant from trivial input competing for attention during training. In the case of reactive dogs, the functional gating capacities that orienting/TAT appears to invigorate seem to help a more adaptive way to cope with novelty and sudden change. Once conditioned, the target-arc stimulus can be presented in anticipation of persistently evocative stimuli to modulate emotional and cognitive overload and prevent the default mobilization of reactive flight-fight adjustments. Orienting/TAT may facilitate the activation or normalization of pathways communicating between parallel preattentive subcortical circuits and attentive cortical networks mediating adaptive behavior in accordance with organized expectancies and calibrated establishing operations. Although these parallel cortical and subcortical systems appear to operate with a high degree of functional autonomy, they share a common autonomic axis that enables dogs to process sensory input and behavioral output in a motivationally coherent way. This organizing axis appears to be activated and modulated by orienting and attending behaviors. The attentional interface brings the demands and pressures operating within and without dogs into directional (drive) and functional alignment and tunes autonomic arousal to accord with changing needs. Adaptive orienting and attending result in increased parasympathetic tone (relaxation), whereas reactive orienting and defensive vigilance result in sympathovagal imbalance (muscular tension and a persistent readiness to act), as reflected in heart-rate changes and indexed by HRV(Billman and Dujardin, 1990; Porges, 1992).

Many of the therapeutic benefits of attention and play therapy are probably mediated through classical conditioning of sympathovagal tone. However, instrumental control over significant events plays a critical role in the way dogs respond to predictive signals. Whereas signals anticipating unconditioned aversive or appetitive events that are perceived as uncontrollable result in sympathetic tone shifts that promote reactive (escaping and confronting) and impulsive (seeking and subduing) adjustments, signals anticipating unconditioned aversive or appetitive events perceived as controllable result in parasympathetic tone shifts that are conducive to proactive adjustments and calming effects. Both appetitive conditioning (Hunt and Campbell, 1997) and aversive discrimination training (Billman and Randall, 1981) produce autonomic changes, evoked by conditioned stimuli, that are consistent with the requirements of an adaptive coping style.

According to cynopraxic training theory, the integration of prediction-control modules results in autonomic attunement and the

adaptive optimization of behavior. In combination, cynopraxic procedures refine selective attention and executive impulse control, increase adaptive modal activity (e.g., social and environmental exploratory behavior), foster optimistic expectancies to social ambiguity and uncertainty, integrate secure social and place attachment, and promote autonomic attunement and autoregulation.

The orienting/TAT procedure can be used to modify preattentive priming effects that negatively bias dogs to respond reactively to visual and tactile stimuli (e.g., sudden change, gestures, body movement, touching, handling, and restraining). To reduce preemptive and reactive processing, evocative stimuli are cross-associated with the auditory target-arc stimulus. The auditory target-arc response is linked with the earliest alert-intention movements shown by the dog in response to the visual signal. For example, in the case of preemptive reactivity to sudden hand movements, the target-arc stimulus (e.g., smooch) is presented just as the dog turns its attention toward the hand movement, followed rapidly by a click, right-hand flick, and delivery of a highly valued reward enclosed in the right hand. The presentation of the well-timed target-arc stimulus and reward immediately following the sudden movement serves to integrate the visual event into a positive network of preemptive associations and expectancies previously established during orienting/TAT. Additional confidence and attraction to the hands is promoted by using the hand as a target stimulus to guide the dog into various postures or movements before delivering the reward. As reactive processing is replaced by improved executive attention and impulse control, controlled exposure is more likely to succeed in organizing adjustments consistent with stable emotional equilibrium and social competence.

Reward: Standard Expectancy and Surprise

The orienting/TAT procedure appears to gradually integrate an attention-axial interface between cortical inhibitory networks and subcortical excitatory loops processing surprise and mobilizing exploitative seeking behavior via the repeated presentation of sequentially ordered events that provide a high level of predictability, controllability, and potential for producing surprise. Cortical surprise is hypothesized to require the existence of a previously established control expectancy, a calibrated establishing operation, and an action, collectively referred to as a *control module*, against which response-produced outcomes are compared, mismatches detected, and the new information integrated into the flexible control module to optimize the dog's future control efforts (see *Prediction Error and Adaptation* in Chapter 10). Orienting/TAT is initiated with a food reward of the least value and smallest size necessary to maintain an orienting/approach response (control module) while conditioning the bridge signal. This reward is referred to as the *standard expectancy* (SE). The SE provides an informational backdrop for comparing the relative value of outcomes produced and for detecting mismatches or positive prediction errors signifying better-than-expected outcomes and surprises. Food rewards of variable sizes, types, and presentations are randomly interspersed among rewards matching the SE value. Whereas orienting stimuli and the food reward are varied, the conditioned reinforcer (e.g., click/"Good") remains constant. The procedure is designed to enhance incentive, promote autonomic attunement, and invigorate attentional functions with cortical reward (surprise). The vocal bridge signal "Good," spoken in a chirped form, is paired with the rapid opening of the hand (visual target arc) and the delivery of the food reward and petting. The vocal bridge signal is also used to support eye contact and sustained attending behavior. Once an attending response (briefly sustained eye contact) is established with the dog's name/smooching and the vocal bridge "Good," talking to the dog, winking, smiling, and head tilting appear to further stimulate the canine SES. A useful technique for transitioning into play is to incorporate directional cues (e.g., gazing, pointing, leaning, and orienting) toward play objects in advance of walking and running toward them. Pointing or looking toward some spot before throwing

the play object in that direction can also help to stimulate interest and coordinated engagement. Directional cues are further integrated as signals by using them to help a dog solve problems (e.g., helping a dog to find a hidden food item). Training a dog to turn right and left, to back up and move forward, and to move in a wide circle so that it is facing away before signaling it to orient can enhance attention control while providing useful preliminary training.

Eventually, the orienting response is integrated into other training objectives (e.g., come, sit-front, eye contact, and following routines) by delaying the bridge until the target behavior is emitted or prompted, whereupon the bridge signal and terminal reward are delivered. As previously discussed, the surprise and active modal strategies emerging in association with orienting/TAT are hypothesized to mediate a cortical/subcortical attention interface or *operant/respondent axis* comprised of instrumental and classical elements (see *Defining Insolvable Conflict* in Volume 1, Chapter 9). As a result of the repeated evocation of surprise associated with the target-arc response (flinch alert), a network of cortical synapses are gradually interwoven into submerged attentional functions, thereby bringing preattentive arousal and reactivity under the modulatory and normalizing influence of executive control. As this critical conduit of information exchange between these parallel neural processing systems is strengthened in the context of orienting/TAT and other cynopraxic therapy efforts, a backbone of order and variety appears to form that enables the dog to engage in greater spontaneity and to show an increased capacity for play and social engagement. The efficiency of orienting/TAT for increasing social spontaneity, play, and social engagement is often nothing short of extraordinary, making it one of the most powerful tools currently available for moderating reactive behavior and integrating an adaptive coping style. To describe the effect of orienting/TAT most succinctly, the dog simply appears to wake up. To attain the multiple cortical and SES benefits of orienting/TAT, the target-arc alert/flinch response may need to be evoked and rewarded several hundred times. When performed properly, preliminary orienting/TAT provides a useful platform for all subsequent reward-based training and cynopraxic therapy efforts. The orienting signals used during orienting/TAT gradually become potent stop-change countermand signals, while the conditioned click and flick bridging signals are enhanced by the attention-focusing influence of such training. The simple shaping procedures used to promote attending and following behavior target and encourage autoinitiated behaviors that improve a dog's sense of control over significant events.

The repeated presentation of contingent rewards (e.g., food and petting) in accord with a standard expectancy, periodic surprise, and occasional disappointment contributes to the organization of an adaptive coping style, biasing the dog to search for signals of reward rather than signals of punishment. Along with surprise-seeking adaptive modal strategies, passive modal strategies are organized by such training toward the adaptive goals of securing reward gains at a minimal risk (i.e., avoiding unnecessary risk taking) and learning to cope with inevitable delays and setbacks (delay-of-gratification skills). Finally, the repeated activation of appetitive and social reward pathways in association with orienting/TAT may mobilize the oxytocinergic antistress system, contributing to feelings of comfort and safety, calm, and well-being (see *Adaptive Coping Styles: Play, Flirt, Forbear, and Nip* in Chapter 6). Orienting/TAT and social engagement therapy also include frontal approach, attending behavior (making and holding eye contact), and submissive ritualizing (sit-stay and down-stay) brought under the control of hand and vocal signals. Reciprocal frontal orientation and mutual gazing appear to initiate a communicative orientation unique to the human-dog relationship, thereby laying the foundation for following, cooperative problem solving, mutual appreciation, and interactive harmony.

The orienting/TAT procedure appears to provide significant benefits for the treatment of a variety of canine behavior problems stemming from attention and impulse-control impairments (see *Locus of Neurotogenesis* in

Volume 1, Chapter 9). The obvious similarities between some of these problems and human psychiatric disorders suggest the possibility that orienting/TAT or similarly organized procedures may have therapeutic value in the treatment of certain of these disorders. Also, many of the social engagement and learning deficits associated with autism are consistent with an axial dissolution between cortical regulatory networks and various subcortical attentional loops necessary for initiating and sustaining social cognition, communication, and engagement. Whether intensive orienting/TAT might provide similar benefits in such cases is unknown; nevertheless, the procedure appears to offer exciting possibilities and novel applications that warrant future investigation.

Attention Therapy, Orienting/TAT Procedures, and Play

1. Target Arc, Orienting, and Approach

A squeak or smooch (S1) sound is followed immediately by a click (S2) and a flick of closed right hand (S3) as the dog orients toward the trainer. The duration of the target arc is approximately 200 to 300 msec, a very rapid succession of events. Although the S1 is presented in various ways from a soft to loud squeak, the timing of S2 is kept constant. The flick and reward combination is variably delayed to occur 1 to 5 seconds after the dog orients.

Orienting and approach to the closed right hand is rewarded by the bridge "Good" spoken just before the hand is opened to reveal the treat.

The SE is established with the smallest effective reward needed to maintain orienting and approach behavior.

Better-than-usual rewards consisting of changes of type, size, context, and delivery are periodically given to produce positive prediction error and incentive shifts (Flaherty, 1996). The cortical reward (surprise) associated with positive prediction error is a critical factor in cynopraxic therapy. In addition to reorienting the dog to reward signals, cortical reward generates active modal strategies that enliven social behavior and promote play.

Forward movement activates the seeking system and is an instrumental part of orienting/TAT. Signaling the dog to orient and thereby to break off the direction of forward movement and to turn toward the trainer has the effect of making the trainer the object of seeking. The effects of this simple stop-change procedure on cognitive function and social engagement are profound and pervasive (see *Attention and Impulse Control* in Chapter 1). The procedure appears to access preattentive cognitive processing, organizes stop-change inhibitory processes, intensifies associative conditioning of the click-and-flick bridging signals, serves to promote feelings of comfort and safety, and activates the SES. In a sense, the squeak and click stimuli result in a series of activating and organizing effects that are analogous to the effect of turning a key to start a car. The simple action of turning the key produces a number of automatically coordinated events that lead to the engine starting and the car working under the guidance of the driver.

2. Frontal Orientation and Coming

As the dog orients and starts moving toward the trainer, the vocal signal "Come" is spoken just before flicking the right hand out to the side.

3. Attending and Submissive Rituals (Sit-Stay Training)

The dog is periodically prompted to sit-front after coming and to make eye contact in response to its name or smooch sound before the bridge "Good" and reward are delivered. The dog is released with the release signal "Okay" and a flick of the right hand, followed by the delivery of a food reward or play. Sit-stay is gradually introduced in the context of enhancing the attending response.

4. Gaze Orienting and Directional Cuing

As the dog orients to come, the trainer points directly over a treat or ball lying on the ground and then places the right hand over it as the dog approaches. The treat is given or

the ball tossed as the dog approaches the spot. Numerous variations are used to encourage the dog to make eye contact and follow gaze and other deictic (pointing) signals.

5. Parallel Orientation and Following

Food or toys can be hidden and the dog supported in its search efforts by periodically getting eye contact and then gazing, pointing, and walking in the direction of the cached item. Found rewards are conducive to significant surprise, and such interaction strongly supports following behavior and cooperation. Coordinated movements shaped with reward serve to integrate behavioral approach and social engagement while promoting cooperation, mutual appreciation, and interactive harmony.

The dog is encouraged to follow near the trainer's side by clicking and prompting it to sit with the right hand, saying "Good" as the dog begins to sit and delivering the treat and petting as the action is completed. The dog is released from the position with "Okay" and prompted to follow along or sent to chase a ball.

6. Dynamic Modal Activities and Play

Various play activities are introduced in accordance with the dog's ability to reciprocate. Intensive orienting/TAT (squeak), cortical reward (click-flick-surprise), attending (frontal orientation and eye contact), and following naturally promote dynamic modal activities and play. The emergence of play during social engagement therapy is an extremely valuable asset in the treatment of behavior problems. Training a dog to play tug, fetch, and catch games can promote joy and enhanced bonding. Retrieve games can be also be used to promote valuable go/no-go inhibitory conditioning effects and to encourage recall habits. Play adds complexity and refinement to the attentional nexus and improves a dog's ability to synchronize behavioral sequences so that they stay in temporal register with the behavioral sequences of the co-player. Competitive play activities, such as tug-and-fetch games, appear to fuse attention onto a point of common interest that promotes friendly exchange, rather than contest, via the differentiation of distinct roles that are equally necessary to initiate and continue the activity. Play continues only so long as it is rewarding for both players—a criterion that serves to promote mutual appreciation (empathy) and fair play, since to take advantage of the other or to neglect the other's needs might result in a loss of play momentum and cause the activity to grind to a halt. Nothing is more revealing of human character and canine temperament than their respective abilities and styles of play. Dogs exhibiting behavior problems invariably exhibit disturbances in their ability to play.

Many features of ball play recommend its use when organizing an adaptive coping style and cooperation. Russell (1936) long ago recognized the value of ball play for organizing adaptive behavior, listing six characteristics of special importance (paraphrased):

1. Chasing a ball involves the whole dog in relation to an object-activity outside of itself.
2. The dog's activity is attentively focused and coordinated with the course of action being pursued.
3. The activity is directed toward a particular goal, that is, picking up and returning with the ball.
4. The goal-directed activity shows a persistence of purpose as evidenced by the dog's willingness to search repeatedly over likely ground for a misplaced ball.
5. The activity is governed by the result produced by it; if the ball is not found, the searching sequence continues for a variable period or until the ball is found, whereupon the search stops.
6. The activity shows evidence of social cooperation and adaptive flexibility, as indicated by the dog's ability to shift from an unproductive search to turn to the trainer for help to find a misplaced ball.

Ball play mediates an intensely focused orientation on an object that the dog would wish to possess but must relinquish to produce the activity that engenders the object with its reward value. Likewise, the trainer shares an interest in the ball as a means to

control the dog's searching and retrieving behavior, entailing that the ball be received and thrown to generate the object-activity valued by the dog. As a result, the dog obtains the object-activity that it graves but sacrifices control of the object to the trainer to maintain the mutually rewarding exchange. For the ball game to continue, both the dog and trainer must give and take advantages with respect to the ball. If the dog grabs the ball and runs off with it, the object of interest is obtained, but the activity that makes it interesting is lost. The ball can be kept in play only by compromise and cooperation in accord with a principle of fairness. As a result of the give-and-take nature of ball play, a sense of fair play and trust (i.e., comfort with social uncertainty) appears to emerge. Tug games integrated into the ball game exemplify the competitive and possessive conflict underlying the activity, that is, the necessity of giving up the object in order to get the valued activity. The relinquishment of the ball to the trainer represents a submissive act of trust based on a belief that the trainer won't selfishly walk off with the object, but will toss it again, thereby meeting the obligation incurred by *accepting* the dog's trust (taking another's trust always involves obligations and responsibilities) and proving oneself as a leader fit to follow. The chase-and-retrieve sequences reflect a cooperative resolution of competitive conflict via the mutual reward resulting from sharing, fair play, and compromise. In contrast, a dog that gets the ball and runs off with it primarily obtains reward via the gratification of selfish and possessive interests stimulated by the owner's pleading for the ball (submissive begging) or by evading attempts by the owner to chase it down, thereby promoting competitive exchanges with little hope for a cooperative resolution. Such play results in interactive conflict, whereby reward is obtained by depriving the other of reward; that is, either the dog or the owner will win or lose. Whatever the outcome, the victory is achieved at the expense of the other and the integration of conflictive tensions and distrust. Under the influence of social attraction mediated by play, such unfair advantages promote social ambivalence by evoking frustration and anger. In the context of cynopraxic theory, tug and ball play, when performed in accord with a principle of fairness and compromise, mediates mutual appreciation (i.e., an attentiveness and responsive to the emotions and covert intent of the play partner) and trust, key transitions in the process of promoting interactive harmony and the integration of a friendly bond.

Finally, in addition to orienting/TAT and play, petting helps to promote a physiological state incompatible with both aggression and fear, providing a viable strategy for decreasing sympathetic arousal in some reactive dogs. Along with play, social rewards (petting and praise) should be integrated into training activities as a major source of reward for all basic obedience work. Not only does petting provide a potent calming and bond-enhancing effect, but excessive reliance on food-related incentives may adversely impact social attachment and affection levels by persistently overshadowing social attraction. Seeking food serves a useful function in basic training and many behavior-therapy efforts, but ultimately appetitive-seeking behaviors should be subordinated to seeking for social acceptance and affirmation while forming an affectionate and playful bond. In dogs showing a deficiency of social attraction, excessive reliance on food rewards may produce a relationship based more on food-getting incentives than on social attraction—a very undesirable outcome. Food-getting incentives are not intrinsically incompatible with social attraction, but appetitive training alone does not necessarily facilitate social attraction. The widespread belief that social rewards do not possess reward value in the absence of primary reinforcement is an operant-conditioning myth contrary to a number of scientific studies (see *Tactile Stimulation and Adaptation* and *Taction and Posture-facilitated Relaxation* in Chapter 6). McIntire and Colley (1967) found that the performance of experienced working dogs (military scout dogs) and naive dogs learning new basic obedience skills (sit, down, come, stay, and heel) showed a reliable decrease in response-latency scores as the result of petting and increased response-latency scores when petting was withdrawn.

In a related study, the researchers found that dogs trained by means of directive control and compulsion in combination with food reinforcement showed increased response-latency scores when the food reward was withdrawn. Interestingly, with regard to the value of social rewards, if the food reward was replaced with petting, the extinction-related latency effects were avoided. Maintaining a balance between petting, play, and food rewards is particularly important in integrating an affectionate bond with puppies.

Insufficient social attraction and appreciation of tactile stimulation appears to play a significant role in the etiology of certain forms of canine intrafamilial aggression (see *Posture-facilitated Relaxation Training* in Chapter 7). Among human adolescents, massage therapy has been shown to reduce aggression, perhaps by decreasing dopamine levels while increasing serotonin activity (Field, 2002). The guided restraint and focused tactile stimulation produced by posture-facilitated relaxation (PFR) training can be use to induce a potent relaxation response in dogs (see *Taction and Posture-facilitated Relaxation* in Chapter 6). The combination of nonthreatening controls, prompts, postural shifts, and restraint serves to promote measured shifts in parasympathetic and sympathetic activation while facilitating autonomic attunement in association with the induction of enhanced comfort and safety. PFR training programs a regulated response correlated with a positive set of expectations in association with a loss of control and increasing vulnerability in association with physical restraint, postural shifting and pressure, and regional manipulations. Rhythmic massage and petting help to further refine the attunement process and set the stage for the dog to transition into a deep relaxation. Repetitive petting appears to exert an adaptogenic effect on HPA drive and may help to integrate antistress and antiaggression effects via the activation of the oxytocinergic system (see *Oxytocin-opioidergic Hypothesis* in Chapter 6). In addition to stimulating changes in major neurotransmitter systems, posture-facilitated relaxation with massage may promote beneficial effects on vagal tone. A dilute odor (e.g., chamomile, lavender, ylang-ylang, or orange) that has been repeatedly paired with posture- and touch-induced relaxation appears to promote arousal conducive to calming and social engagement, perhaps by promoting an ambience of safety and conditioned relaxation. The autonomic attunement mediated by PFR training is bidirectional, with both the person providing the relaxation training and the dog receiving it benefiting from the enhanced sympathovagal balance and calming brought about by the experience.

Quality-of-Life Matters

Survival Modes and Allostasis

In addition to providing modal direction to species-typical behavior and mediating epigenetic adaptations appropriate to age and survival needs, specialized phylogenetic survival modes (PSMs) appear to be conserved from the dog's evolutionary past and activated by changing social or environmental conditions. PSMs are expressed cyclically throughout the canine life cycle in a relatively orderly way in the process of coordinating biobehavioral adjustments conducive to adaptation and survival. Benign PSMs promote adjustments conducive to dynamic autonomic equilibrium (sympathovagal balance) and long-term survivability. According to the survival-mode hypothesis, epigenetically programmed survival modes are variably activated and deactivated by environmental changes determined to be better or worse than ordinary, as indexed by the activation and tone of the HPA system, autonomic attunement/misattunement, and the mobilization of allostasis, that is, the coordinated adjustments needed to maintain biological integrity and stability in the context of change (Wingfield, 2003). The activation of a PSM is variably intrusive and compelling, ranging from a condition of motivational transparency overlaying everyday activities (appetites and preferences) to intrusive motivational imperatives (modal drives) that cannot be ignored without enduring significant agitation or distress. Autonomic networks probably coordinate the expression of modal drives that subserve PSMs activated or deactivated in association with social

exchanges (attunement/misattunement), QOL shifts, and allostatic changes associated with the switching on and off of the HPA system. The PSM defines in advance the class of behavior that will produce reward; it also determines whether a particular outcome will be satisfying.

The survival-mode hypothesis postulates that adaptation is relative and dependent on an organism's ability to cope by staying in step with the PSMs active at any given moment via the organization of appropriate control modules and adaptive modal strategies. Since the survival mode appears to determine in advance the class of behavior and outcomes that will produce reward, the activated mode exerts a global organizing effect on behavior, giving it motivational direction via modal drive. By these means, *instinct* exerts a profound influence on behavior without usurping executive functions. In the context of modal shifting or switching, reactive or rigid (compulsive/impulsive) adjustments to changes in motivational direction promote autonomic imbalance and negative mood, whereas flexible adjustments in harmony with modal change promote autonomic balance and positive mood. From a human perspective, obtaining gratification in harmony with modal drive and PSMs might be akin to obtaining meaning and contentment from behavioral efforts, whereas gratification obtained in conflict with modal drive and PSMs might produce subjective feelings of ennui, meaninglessness, and despair. These observations emphasize the relative independence of the cognitive and emotional effects produced by gratification and reward. According to cynopraxic theory, adaptive success is achieved by maintaining a dynamically stable state (allostasis) in the process of integrating secure social and place attachments via the optimization of comfort and safety (security) and the mobilization of adaptive modal strategies that are in harmony with survival modes and drive.

The activation and deactivation of PSMs is the coordinated outcome of countless neural networks and neurotransmitter systems, but DA, 5-HT, and NE systems appear to play prominent roles in the process. The present hypothesis speculates that oxytocin and AVP act as cofactors or moderators of DA, 5-HT, and NE activity in the process of activating, modulating, and deactivating PSMs in response to social and environmental stressors. Under worse-than-ordinary conditions (adversity), DA, 5-HT, and NE systems may be configured into survival modes aimed at avoiding danger and harm (autoprotective or loner mode), causing a dog to respond with increased anxiety, irritability, impulsivity, and aversion in response to social novelty and sudden or unexpected change; whereas, under the influence of better-than-ordinary circumstances, neural activity and traffic may be rerouted to produce modal changes conducive to calming, social integration, invigorated autonomic tone, and an adaptive coping style.

5-HT is hypothesized to contribute to the maintenance of stability over time against which backdrop modal changes weave in and out of sync and phase. The stability of biobehavioral systems is expressed in the form of biological rhythms that give rise to consistent adjustments having a cyclical or waveform shape and regularity (e.g., sleep/wake cycles) and expressed in the daily patterns of activity and rest, vigilance and foraging, hunger and satiation, and social comfort seeking and giving, as well as in various functional and dysfunctional adjustments to social and environmental stressors. In coping with adverse conditions, the serotonergic system may undergo harmful modifications via allostatic load and overload, impairing its ability to maintain a condition of flexible stability over time, perhaps causing behavior to become increasingly rigid (compulsive or impulsive). The increased 5-HT_{2A}-receptor binding potential shown by dogs exhibiting impulsive aggression (Peremans et al., 2003) may represent the cumulative allostatic load resulting from the serotonergic management of stress adjustments stemming from chronic HPA or SAM hyperdrive.

PSMs integrated under the influence of optimal developmental conditions are behaviorally invigorative and unifying, switching on and off at appropriate times and durations to enhance behavioral adaptation. However, with dogs exposed to adverse developmental stress,

PSMs may become stress sensitized and reactive, turning on impetuously to minimal triggers or switching off sluggishly or remaining chronically active or inactive. The activation of flight-or-fight survival modes and drive by conditioned and unconditioned stimuli anticipating imminent harm is adaptive, but many reactive dogs appear to remain persistently aroused to a state of vigilant readiness under the influence of a dysfunctional flight-or-fight mode. The resulting reactive coping style and allostatic load/overload may severely impair a dog's ability to adjust competently to household stressors. Although dysfunctional survival modes may remain relatively quiescent under auspicious environmental conditions that place few demands on the dog, they may be activated in response to social conflict and stress or as the result of integrating the PSM into social behavior emerging epigenetically at the time of puberty and early adulthood. Functional PSMs that ordinarily mediate adaptive adjustments may become dysfunctional (hyperreactive or hyporeactive) as the result of developmental stress. Instead of mediating adaptive behavior, the dysfunctional PSMs may be variably modified and integrated into a persistent state of sympathovagal imbalance producing a vulnerability to express generalized anxiety, depression, impulsivity, compulsivity, hyperactivity, separation distress, and aggressive reactivity. Under conditions of social ambivalence and entrapment, the dysfunctional PSM may lower reactive thresholds and predispose the dog to panicogenic impulsive or reactive aggression and numerous other adjustment problems. Once toggled on by stress or epigenetic triggers, the dysfunctional PSM may profoundly disrupt normal processing and impair the dog's ability to toggle off the malignant PSM. As a result, the dysfunctional mode may become progressively autonomous, perseverant or cyclic, and maladaptive in the process of degrading or abolishing executive control and fostering a reactive state of autonomic instability.

Quality-of-Life Index

Among dogs, the activation of survival modes is indexed by the release of circulating hormones and the activation of modal drives giving motivational direction to behavior. These chemical signals are hypothesized to configure into molecular keys that switch on and off potent PSMs affecting mood and behavior, including courtship, pair bonding, reproduction, social organization, maternal care, and territorial behavior. In addition to PSMs regulating the expression sex-related behaviors, survival modes are expressed in association with the release of chemical signals indexing stress-related changes. The diversified functions of AVP and oxytocin are consistent with the routing of modal shifts conducive to social integration or a loner-dispersal strategy (see *Diet Change and the Integrate-or-Disperse Hypothesis* in Chapter 7).

According to the integrate-or-disperse hypothesis, oxytocin facilitates social bonding, integration, and calming under the influence of environments perceived as safe and biologically optimal (adaptogenic), whereas, under the influence of environments perceived as unsafe or biologically suboptimal (stressogenic), AVP/CRF may cause the SES to retract and to promote dispersal and entrapment tensions, agitation, irritability, intolerance, and withdrawal (depression). Under the influence of social and environmental stressors that stimulate increased SAM activity, the HPA-system activity of susceptible dogs may be cranked up into a state of HPA hyperdrive, thereby mobilizing an allostatic state conducive to a reactive coping style that may be expressed in association with a defensive autoprotective mode or a defeat mode, depending on the allostatic vulnerabilities and traits expressed by the dog. The defeat mode promotes generalized anxiety, impassivity, and social withdrawal, whereas the autoprotective mode is associated with heightened anticipatory anxiety, sensory vigilance, and reactive readiness. By contrast, in addition to promoting antistress and calming effects via the activation of the flirt-and-forbear antistress system, oxytocinergic-opioid interactions with other neuropeptides and neurotransmitters may configure an intricate neuroregulatory network that promotes allostatic normodrive, social engagement, play and activity success, and modal strategies

conducive to the organization of an adaptive coping style.

A dog's ability to integrate harmonic relations with people and other dogs inside and outside of the home depends on the presence of secure social and place attachments. The quality of social attachments is positively correlated with a variety of QOL factors, including diet, exercise, somatic and cortical reward, perceived safety, play, freedom of movement, exploration, and access to diverse social and place experiences. A high QOL index is hypothesized to promote social attraction and drive consistent with secure attachments and play, whereas a low QOL index tends to promote social repulsion and withdrawal, dispersive tensions, and autoprotectiveness. According to the integrate-or-disperse hypothesis, moving from an adequate QOL index to a higher QOL index tends to promote tolerance for social novelty and sudden change, but only insofar as QOL enhancements are linked with an increase in affiliative exchange. Improving a dog's diet or increasing exercise (e.g., putting the dog outdoors) without simultaneously increasing positive social interaction [e.g., tactile stimulation (petting and massage), socialization, and reward-based training activities] may increase its vulnerability for reactive behavior in response to social novelty and unexpected change. In contrast, dogs transitioned from an adequate QOL index to a suboptimal QOL index may respond in an opposite way to increased proxemic exchange (e.g., close contact, handling, and tactile stimulation) by showing signs of social avoidance and withdrawal or decreased exploration of novel situations. Augmenting a dog's QOL index without supplemental social interaction and training or degrading its QOL while simultaneously increasing demands for exchanges with unfamiliar persons or exploring novel environment and things may promote counterproductive autonomic misattunement dynamics (see *Diet Change and the Integrate-or-Disperse Hypothesis* in Chapter 7).

Cynopraxic training procedures typically embody both QOL enhancements and intensified social exchange with the goal of promoting mutual appreciation and interactive harmony. As such, play is an ideal cynopraxic procedure because it incorporates QOL enhancements associated with physical exercise and the activation of a variety of drive systems while simultaneously increasing the quantity and variety of affiliative exchanges. As such, increased social and object play should promote enhanced responsiveness to social novelty and sudden change, whereas decreased social play appears to increase the risk of reactive arousal to ambiguous or uncertain social exchanges between the dog and the nervous or insecure attachment object and increase latency or reduce the amount of exploratory behavior in response to novel objects or places. An opposite set of effects should flow from training procedures that systematically decrease social and appetitive stimulation (withholding of affectionate interaction, play, food, tactile stimulation, and access to toys) while increasing social isolation, physical restraint, and confinement—practices that are generally referred to as emotional and deprivational abuse by the pediatric community (Golden et al., 2003) but are commonly used as therapy to treat canine separation-distress and dominance-aggression problems on the basis of compelling the dog to detach or coerce a change of attitude with respect to perceived social rank by compelling detachment from insecure social and place attachments. Such procedures seem counterintuitive and contrary to the basic tenets and goals of cynopraxis. In the case of dogs showing intrafamilial autoprotective aggression in association with unfairness and incompetence and a loss of trust, the use of social, emotional, and appetitive deprivation procedures should only increase social ambivalence, dispersive tensions, and entrapment dynamics in the process of elevating the dog's irritability and reactivity in response to ambiguous social exchanges. These collective changes in response to deprivational establishing operations may actually increase the risk of impulsive aggression rather than helping to reduce it. Attempting to coerce an indulgently dependent and reactively incompetent dog into submission by abruptly extracting insecure attachment relations or refusing access to attachment objects and places associated with

comfort and safety may only serve to exchange dependency by indulgence for dependency by domination; nothing has essentially changed, except that the interaction has now become dramatically more volatile and imbalanced in an opposite direction.

Environmental improvements and degradations affecting a dog's QOL appear to mobilize distinct survival modes conducive to enhanced social integration or dispersal (entrapment). Social interaction incompatible with the educed mode appears to result in social anxiety and aversion. This general hypothesis is central to cynopraxic theory, whereby interactive changes conducive to enhanced bonding are coordinated with environmental changes conducive to an improved QOL, thereby simultaneously integrating secure social and place attachments while promoting autonomic attunement (calming), social bonding and trust, and emotional and drive propensities (i.e., affectionate playfulness) incompatible with aggression. Attempting to improve interaction and integrating consistent, fair, and structured interaction via ICT without simultaneously improving a dog's QOL is problematic and may only increase insecure attachments or serve to activate autoprotective dispersal/loner tensions, whereas improving a dog's QOL without integrating social interaction and affiliation based on a principle of fairness may actually heighten social insecurity and dependency rather than helping to reduce it. Even slight modifications of diet may exert pronounced changes in a dog's social behavior (see *Fat, Cholesterol, Fatty Acids, and Impulsive Aggression* in Chapter 7). For example, supplementing the diet with fat or polyunsaturated fatty acids (PUFAs), especially omega-3 [eicosapentanoic acid (EPA) and docosahexanoic acid (DHA)] may enhance a dog's ability to cope with emotional stressors and reduce impulsive behavior, perhaps via the improvement of serotonergic transmission (Buydens-Branchey et al., 2000). However, McCreary and Handley (2000) could not produce any change in 5-HT_{1A}- or 5-HT_{2A}-mediated behaviors in rats treated with a cholesterol-reducing drug for nearly 2 months, suggesting that the adverse effects of low cholesterol on stress-related behavior and impulsivity may be mediated by another system. Another possible target of omega-3 therapy may be stress-related proinflammatory cytokines that are produced in association with allostatic hypodrive and linked with depression and irritability. A recent report lends some support to the hypothesis that low cholesterol levels (hypocholesterolemia) may play a role in the etiology of certain forms of autoprotective impulsive and reactive aggression. The researchers found that dogs diagnosed with dominance aggression showed low total cholesterol, low serum triglycerides, and low high-density lipoprotein cholesterol (HDL-C) in comparison with nonaggressive controls (Penturk and Yalcin, 2003).

In addition to dietary and social considerations, QOL enhancements should focus on exercise, play, grooming, activity success and freedom of movement, and varied environmental activities contributing to a state of canine well-being. Recording the amount of time that a dog spends crated or otherwise socially isolated during the day and night provides a useful QOL and social attachment indicator. Excessive crate or outdoor confinement is contrary to cynopraxic goals and typically points to significant interactive conflict and dispersive tensions between a dog and household. Cynopraxic training and QOL improvements are organized to address these disruptive influences comprehensively.

Opening the Training Space

In comparison with animals trained under the constraints of the laboratory, a typical family dog is exposed to a far greater diversity of arousing stimuli, extraneous reinforcement opportunities, and adjustment demands, some of which are potentially harmful to it or to others with whom the dog comes into contact. Unable to restrict a dog's access to these opportunities or to block entirely the undesirable behaviors that dogs are apt to show, cynopraxic trainers are compelled to construct a behavioral analogue to the physical restrictions and controls found in the laboratory setting via the agency of inhibitory conditioning

(McIntire, 1968). Establishing inhibitory control is particularly important for dogs exhibiting attention and impulse-control deficiencies affecting their ability to accept social limits, to delay gratification, to regulate emotion, and to control aggressive behavior. To address such issues properly, a training space is configured at three points of interaction: pulling, jumping up, and biting. The training space is established to provide a social context of interaction conducive to reward-based training and play.

The first step in this critical process focuses on the inhibition of pulling into the leash. Instead of physically holding the dog back and causing it to strain into the leash, the impulsive dog learns to regulate its behavior within the limits set by the leash in the context of controlled and slack-leash walking. Deliberately allowing such dogs to pull into a dead leash is misguided and potentially harmful (see *Walking on Leash* in Chapter 1). Not only is the persistence and novelty seeking of such dogs virtually inexhaustible, the frustration produced by such efforts will only cause impulsive dogs to pull harder in the process of activating and conditioning oppositional reflexes. Although the passive restraint afforded by a muzzle-clamping halter may be more effective and less prone to the foregoing effects, such restraint is not without significant potential problems. Impulsive dogs often show considerable arousal and distress when first exposed to halter restraint. Many of these dogs struggle persistently and violently to escape by scraping at the halter with the front paws; by twisting, flailing about, falling down to rub their head against the ground; or by pulling back and shaking their head violently back and forth in an effort to break free of the collar (see *Aggressive Barking, Lunging, and Chasing*). The latter maneuver, however, results in a severe and persistent clamping action across the muzzle. After repeated exposures of this kind, the dog may finally recognize that its efforts to escape are futile and simply give up, appearing to adopt an attitude of resignation and surrender to the owner's domination. Halter training of this sort does not appear to translate into avoidance and inhibitory conditioning of the sort needed to facilitate improved attention, impulse control, and autonomic regulation. As a result of such mishandling and improper exposure to halter restraint, the dog, discovering that the aversive restraint is inescapable, may move from an active state of hyperarousal into a passive state of behavioral inhibition and hypoarousal resembling learned helplessness—and both states reflect autonomic dysregulation but from opposite extremes.

Introducing dogs to halter restraint with a nonclamping halter in the context of reward-based training can mitigate many of these problems. The nonclamping halter is designed to prevent the clamping action that occurs when dogs attempt to back out of muzzle-clamping halters. When introducing the muzzle-type halter to impulsive or reactive dogs, it is most safely and humanely accomplished with two leashes: one attached to the muzzle-clamping loop and the other attached to a flat-buckle collar or limited-slip collar. The arrangement allows a dog gradually to accommodate the unfamiliar and potentially threatening feel of the halter-clamp action seizing its muzzle, thereby avoiding a potent aversive event that may needlessly link the device with fear, pain, and panic. First impressions are powerful and lasting, especially in the case of things that trigger threat arousal and sustained pain, or impose a condition of inescapable aversive stimulation, while simultaneously disabling a dog's primary means of defense and blocking its means to flee—psychologically nothing could be more traumatic for reactive dogs. A similar state of affairs and helplessness effects appear to ensue as the result of improper crate training, whereby a dog is forced into a condition of inescapable restraint and social isolation, and then left to cope with escalating separation distress and emotional dysregulation. In both cases, the novelty of the events and the loss of control over threatening situations result in intense and persistent sympathetic hyperarousal and finally activate the immobilization system (helplessness) as the stimulation is perceived as inescapable. Since crates and halters are readily available to novice owners with little or no significant instruction, great potential harm is done to impulsive or reactive dogs by such instruments of restraint. It is distressing to consider the miserable state of a young energetic dog that spends 16 to 18 hours a

day *stored* in a crate barely big enough for it to lie down, and whose only respite from the drudgery and tyranny of such confinement is to be taken outdoors periodically on a muzzle-clamping halter to eliminate. As a result of these welfare concerns, pains are taken to introduce the crate and halter in uneventful stages and to use such mechanical suppressors of behavior in the least intrusive and minimally aversive ways necessary to achieve training objectives in a timely and humane manner and then to fade their use as these training goals are met.

Despite the potential for abuse and misuse, if properly introduced and used in the context of reward-based training, the muzzle-clamping halter can help to provide head and jaw control that makes handling aggressive dogs safer for both the trainer and others coming into the dog's vicinity. For dogs with a history of aggressive behavior toward visitors, the muzzle-type halter gives the handler an effective means to restrain a dog that might become aggressive unexpectedly during training. Consequently, despite valid concerns, the potential benefits of muzzle-clamping halters for managing and controlling aggressive dogs appear to outweigh the manageable risks. A reactive dog should be kept on a muzzling halter and leash or a muzzle for the sake of added head control and restraint, but other collars are typically selected for inhibitory training purposes. For example, the often-maligned and misused prong collar can be used to rapidly establish active limits on pulling excesses with little risk of harm to the dog, thereby opening a viable training space and allowing the trainer to focus more exclusively on other behavior-therapy objectives. Although giving the appearance of a medieval torture device, the prong collar is a sophisticated training device with a number of obvious and not-so-obvious features that make it extremely versatile and useful in the context of controlling highly motivated and impulsive behavior and in developing effective go/no-go and all-stop inhibitory control.

Inhibitory Conditioning

The selection of a training collar and the techniques used for inhibitory training is guided by a dog's particular temperament, sensitivity, history of training, and its owner's ability and commitment to learn the skills necessary to use the equipment properly (see *Training Tools* in Chapter 1). A tool of considerable value in this regard is the limited-action slip collar with or without a fixed-action halter. This training collar gives skilled trainers the means to deliver a precise level of stimulation, ranging from gentle pulsing and directive prompts to a *dead-halt saccade*. The term *saccade* is borrowed from horse training and refers to a sharp action applied to the reins. The word also refers to the sudden and forceful movement of a violin bow that causes the sound of two or more strings being struck sharply at once. In any case, the function of the saccadic prompt is to inhibit impulsive behavior rapidly without inducing disorganizing anxiety and fear. The saccade is always associated with an abrupt release of leash slack immediately before stepping back and anchoring the leash with both hands in front of the torso, just above the center of gravity, before shifting back and tensing as the dog hits the end of the leash. The sequence establishes a close forward association between the release of leash slack and the saccadic event. Yanking against a taut (dead) leash is not a saccade, and such uses of the leash should be avoided. Allowing a dog to pull into a dead leash is virtually always counterproductive and indicative of incompetent dog-handling skills. The saccade is followed by vocal reassurance and sustained petting around the underside of the neck and continues widely over the dog's body, followed by massage on the back of neck and shoulders to further facilitate calming and autonomic attunement. The saccade often produces a one-trial learning effect, whereby the dog learns to rapidly stop whatever it is doing at the moment the leash slack is dropped (all-stop response) or to turn its attention toward the trainer (stop-change response), thereby reentering the training space.

The directive saccade reduces stress while establishing inhibitory control and entraining parasympathetic tone incompatible with reactive arousal. The systematic entrainment of parasympathetic tone while mediating an adaptive coping style promotes emotional

states incompatible with impulsive and reactive adjustments. The autonomic effects mediated by directive training are key to understanding how such procedures help to increase the confidence of shy dogs and reduce the aggressiveness of bold dogs. Contrary to erudite opinion to the otherwise, such procedures do, in fact, promote beneficial change and do so without increasing reactive emotion or behavior. However, aversive events that lack predictability or controllability are stressful to dogs and should be avoided. Inhibitory training is typically carried out with the dog outdoors while it is engaged in energetic and non-specific seeking of drive-activating stimulation.

The changes in parasympathetic tone by means of leash prompts and saccades may be mediated by pressure stimulation of arterial baroreceptors located in a dog's neck. When placed correctly on the neck, the training collar closes over the carotid sinus, the brief compression of which may result in the generation of an electrical signal that causes the heart to slow down (Seagard et al., 1999). Afferent vagal signals also leave the heart and communicate the change in cardiac rhythm to the brainstem, which may in turn activate cortical and limbic regulatory centers in the process of tuning sympathovagal state arousal to enable the dog to cope proactively with the abrupt and surprising change. Although changes in heart rate following carotid stimulation quickly abort, the afferent vagal signals returning to the brain may shift autonomic balance to match the physiological requirements needed to facilitate improved orienting, maintain the all-stop response, or promote sustained attention—changes that are often directly reflected in a general calming and improved attention and impulse control that immediately follow such training events. According to cynopraxic training theory, the directive prompt evokes an emotional establishing operation conducive to the expression of behavior that enabled the dog to control similar events successfully in the past.

The autonomic changes produced by the directive event are associatively linked with various antecedent stimuli (e.g., dropping the leash slack, smooch sound, and all-stop signals) that are arranged to occur immediately prior to the directive prompt or saccade. As a result, these conditioned stimuli acquire the capacity to shift parasympathetic tone in the absence of the unconditioned vagal reflex evoked by the leash prompt. The petting and vocal comforting that follow directive events may amplify or sustain vagal tone and actively oppose sympathetic activation, thereby helping to promote sustained attention and calmness. The power of traditional dog-training techniques to calm overly reactive and impulsive dogs appears to be related to these potent and complementary effects of the directive leash prompt and tactile stimulation for tuning sympathovagal tone. As such, the leash prompt is a corrective event insofar as it *corrects* autonomic tone that facilitates reactive behavior. The combination of leash prompting followed by petting and praise serves to facilitate autonomic tone conducive to adaptive behavior, calming, and a secure *connection* mediated by autonomic attunement. Dogs appear to have evolved an autonomic nervous system designed to cope with such training, exhibiting significantly increased parasympathetic tone than found in humans (Little et al., 1999) and wild canids (Fox, 1978). The brief pressure of a leash prompt stimulating baroreceptors located in the carotid sinus appears to produce a significant parasympathetic response while promoting enhanced attention and impulse control, whereas steady pulling (horizontal hanging) or forceful yanking into a dead leash appears to agitate the dog and to further disturb executive control functions.

An impulsive dog is generally walked in a controlled position at the handler's left side, with the dog's hip aligned with the handler's left leg. The handler holds the leash in the left hand as described in Chapter 1 (see *Leash Handling*). The dog is prompted to orient while on leash with a smooch or squeak sound and later with its name. As the dog gives a flinch alert to the orienting signal, a click is delivered, followed by a right-handed flick and delivery of the reward by tossing it to the dog. The reward is given to the dog while the trainer maintains forward movement or after stopping and prompting a sit

response. If the dog becomes distracted or moves out of position, the orienting signal is given, an abrupt stop or right turn-away from the distraction is performed, or the dog is prompted back into the proper starting position (see *Walking on Leash* in Chapter 1), as required by the circumstances. The standard reward is periodically interspersed with a highly valued food reward (surprise) and petting. Surprises are frequently timed to occur in association with antecedent praise and petting. In addition to varying the size and type of the reward, sustained rewards with several small treats can be highly effective, especially with respect to shaping introductory attention (eye contact) and stay training. Surprise can also be generated by the introduction of periodic bouts of ball play or other forms of play as appropriate for a particular dog. Go/no-go inhibitory training can be effectively introduced in the context of periodically saying "Wait," stopping, and prompting the dog to stop with a wave of the right hand and gentle leash prompting if necessary before continuing on. Go/no-go training can be mastered at the door before going for a walk, before coming inside after a walk, before going up and down steps, before allowing a dog to take its meals, and on numerous other situations in a manner consistent with ICT. Go/no-go countermand signals can also be developed in the context of ball play. Once a strong ball drive and routine are established, the dog can be taught to delay gratification and wait (no-go) before it is prompted to chase the ball. "Wait" functions as a cancellation signal countermanding the impulse to chase the ball while imposing a no-go condition that eventually results in the reinstatement of the original impulse via the go signal "Take it," releasing the dog to fetch the ball.

Counterconditioning: Limitations and Precautions

When performed by skilled trainers, appetitive counterconditioning, reward-based training, and play can integrate a significant amount of behavioral control, but only within the context of a reliable training space formed by setting limits on reactive/impulsive behaviors. Typically, the modification of impulsive behavior incorporates a combination of strategies, depending on its severity, including preemptive prompts (e.g., diverters and disrupters), stop-change conditioning (e.g., orienting/TAT), go/no-go (e.g., "Wait"), all-stop conditioning, and intensive basic training. All of these elements are critical for establishing a viable platform for graduated counterconditioning within the home environment. Technically, counterconditioning is a classical conditioning procedure, but, in practice, classical and instrumental procedures are inextricably intertwined and wedded. An effective counterconditioning stimulus not only serves to evoke emotional arousal incompatible with reactive emotional conflict, but it may also reinforce instrumental behavior incompatible with aggressive behavior. Generally, counterconditioning procedures are useful in three ways, reflecting the complementary effects of classical and instrumental conditioning: (1) counterconditioning stimuli elicit appetitive and emotional responses that are incompatible with or overshadow competing negative reactions elicited by the target, (2) counterconditioning stimuli (e.g., food, taction, and play) can function as appetitive and emotional establishing operations, and (3) counterconditioning stimuli can be used as rewards to shape prosocial behavior.

Pavlov (1928) tested the efficacy of graduated exposure, appetitive counterconditioning, and instrumental training for controlling reactive guarding behavior in dogs housed under laboratory conditions. The two dogs treated by Pavlov showed reactive aggression toward any person, other then the experimenter, who approached them while they were restrained in an experimental harness. When out of the harness and walking freely about the experimental room, the dogs tolerated the approach of strangers. When away from the experimental setting, the dogs were friendly and showed no signs of aggressive behavior. At such times, they showed a social indifference toward the experimenter and would allow others to approach and even strike the experimenter without showing any sign of resentment toward the action. Interestingly, Pavlov found that the level of aggression

exhibited by the dogs was strongly influenced by the character of the experimenter. When in the company of an experimenter who displayed a commanding control style with positive and negative aspects, the dogs showed a significant increase in aggression toward people entering the experimental room in comparison to the aggression levels shown when the dogs were in the company of a more reserved experimenter who displayed a more circumspect control style. In the latter case, strangers could enter the room without evoking aggression, so long as they did not make any sudden movements, whereas, in the former case, the dogs were stimulated into a "furious rage" when approached.

The different control styles exhibited by the two experimenters described by Pavlov is consistent with the low-power and high-power autonomic/cognitive profiles described by Bugental and colleagues (1993 and 1997). The increased aggressive reactivity while restrained in company with the reactive experimenter may be due to autonomic changes resulting from inescapable exchanges with an emotionally labile (low power) and ambivalent attachment object, whereas the reduced aggressive reactivity expressed while entrapped with the reserved experimenter may reflect the autonomic effects of inescapable exchanges with an emotionally stable (high power) and ambivalent attachment object—findings that may be of significant value for evaluating the effects of person on intrafamilial and extrafamilial aggression. In short, the highly specific nature of the provoking situation (restraint in an experimental harness) suggests the possibility that the inescapable exchanges with the two experimenters served to differentially modulate the aggressive reactivity shown by the dogs via different stimulatory on autonomic tone. These observations raise the possibility that entrapment with an ambivalent attachment object may facilitate the expression of different types of extrafamilial aggression, dependent on their control style and autonomic tone, perhaps giving clues to the etiology of dogs that express habituating versus nonhabituating watchdog scripts.

Pavlov tested two counterconditioning procedures for potential efficacy in reducing the reactive guarding behavior of these dogs. One procedure used appetitive counterconditioning to condition stimuli emanating from his person (e.g., shape, odor, and voice) with food to cause his presence to evoke arousal incompatible with aggression. A second dog was trained in similar fashion with the addition of an instrumental response not trained in the first dog. The training process was performed by Pavlov himself and lasted for 2 months, concluding with several days of testing to evaluate the effects of the procedures. Training was initiated by feeding the dogs by hand in a minimally provocative situation, the main hall, where both dogs were friendly with people. Feeding by hand was performed to bring the scent of the experimenter into the composite conditioned stimulus (CS). One of the dogs, Usatch, was trained to respond to the word "sausage." Conditioning was performed by saying "Sausage, Usatch," and then reaching into a pocket, removing a glass case, opening the case, and selecting a piece of food that was delivered by hand or dropped on the floor. Next, Pavlov developed a discrimination procedure, whereby he stood among a group of people before calling to the dog and rewarding him. To foster contextual generalization, the dogs were called from unusual locations with a variable tone of voice, thereby invigorating the auditory component of the composite CS. The second dog, Calm, was given similar training, except that he was required to sit and to give a paw with the command "Sit down; give your paw" before obtaining the food reward.

Contrary to anticipated results, the restrained dog launched into a fierce attack mode as the trainer entered the room, just as it had done with any stranger entering the room in the past. Counterconditioning by pairing food with the person CS proved inadequate and failed to compete with aggressive arousal. Additional control (e.g., interrupting the barking response) was evoked by commanding Calm to sit and to give its paw or by calling Usatch by name, but the strength of these CSs and command components to restrain aggressive arousal were fragile and rapidly diminished as the trainer attempted to approach closer to the dog and experimenter,

whereupon the dog again became aggressive. However, if the trainer reached into the pocket usually containing food, the dog could be persuaded to allow a slight additional advance, followed by more if the trainer withdrew the *empty* glass container previously associated with food. A full approach to Calm could be achieved only by showing the dog the glass case containing food as the trainer moved forward. If the dog was fed from the trainer's hand, it allowed him to threaten and to strike the experimenter lightly, actions that would have previously led to uninhibited attack.

Pavlov's investigation appears to draw into question the viability of counterconditioning and sit-stay training as stand-alone procedures in the treatment of aggression problems. The study strongly recommends that these procedures, as used in many contemporary applied animal behavior systems, should receive experimental and controlled clinical investigation for efficacy. Despite their widespread use and virtually unquestioned acceptance, neither procedure has been proven to reduce aggression. Although counterconditioning may palliate or antagonize the arousal elicited by aversive stimuli and facilitate the disconfirmation of previously acquired conditioned threat expectancies, preattentive biases in association with trait anger and anxiety may nevertheless persist or be rapidly reinstated despite the most conscientious counterconditioning efforts. The acquisition of food may momentarily quell aggressive arousal, but the nonfamilial status of a visitor may persistently evoke distrust, suspicion, and potential for animosity. Dogs expressing a rigid watchdog script may be genetically programmed to resist counterconditioning effects actively (see *Flexible versus Rigid Watchdog Scripts*). Counterconditioning applied to reduce state anxiety associated with extrafamilial aggression may rapidly decrease signs of defensive behavior but may not reduce the dog's distrust or propensity for offensive behavior, operating under the motivational influence of trait anxiety and anger. Problematically, state anxiety and anger (agitation) associated with reactive conflict appear to be more rapidly decreased with counterconditioning than are trait-anger propensities causing the dog to confront the intruding stranger. Further, the mere reduction in agitation does not automatically increase social attraction and the dog's ability to integrate friendly relations with a visitor. Furthermore, despite the reduction in overt reactive behavior, conditioned autonomic responses may persist or worsen over time via schizokinetic and autokinetic mechanisms (Gantt, 1944; Dykman and Gantt, 1997). As a result, even though a dog appears to be more relaxed, it may still remain under the influence of an unstable sympathovagal equilibrium that can unexpectedly shift and trigger aggressive behavior.

Many reactive and impulsive dogs appear to be affected by disturbances of their ability to engage and disengage attentional resources and to shift flexibly in and out of motivational states necessary to explore and habituate competently to novelty, learn to relax in the presence of unfamiliar persons and places, and respond in a neutral or positively biased way to unexpected or sudden changes. These deficits appear to develop in association with chronic defensive arousal (anticipatory anxiety) and stress. The allostatic load associated with being constantly on guard and at the ready for the worse to occur may result in the disengagement of critical social and attentional resources that are needed to regulate and attune autonomic tone to changing circumstances, perhaps causing the dog to rely on subcortical systems for the processing of social novelty and for mediating autonomic adjustments via the activation of the flight-fight system. Consistent with such a hypothesis, extrafamilial aggressors often show a persistent inability to habituate and relax. Overly vigilant and reactive dogs cannot disengage attention from the novel aspects of an unfamiliar person to turn attention toward more positive and familiar associations that might serve to activate the social engagement system—a system that remains inactive so long as the dog remains apprehensive. In the absence of active social attraction, the persistent vigilance exhibited by such dogs is shadowed by a preemptive readiness to attack (see *Collicular-Periaqueductal Gray Pathways and Reactive Adjustments*). Bottom line, despite

the most dedicated counterconditioning efforts, aggressive dogs may continue to harbor a negative bias toward nonfamilial persons and respond to them as potential threats.

A related stumbling block impeding the effectiveness of counterconditioning is associated with the timing of incompatible appetitive stimuli. Aggressive arousal elicited prior to the presentation of the orienting stimulus or incompatible diverter (e.g., food, petting, or play) may shield sensorimotor gating, orienting responses, and aggressive intention movements against beneficial counterconditioning effects. The key to avoiding such problems is to evoke preemptive establishing operations, establish effective orienting and attention control, and develop reliable instrumental control. Targeting preattentive processing and the preemptive emotional arousal resulting from it figures prominently in integrating an adaptive coping style and reducing reactive behavior. However, habitually presenting diverters and disrupters after a dog has already reached the point of showing overt agonistic intent is contrary to effective behavior therapy. Orienting/TAT appears to be useful for limiting the adverse effects of reactive preattentive processing and, together with inhibitory conditioning, should be an important part of preliminary training efforts. Essentially, the conditioned target-arc stimulus (e.g., squeak, smooch, or whistle) serves to establish preemptive processing and arousal incompatible with aversion, making it easier to integrate more positive associations.

PRECAUTIONS FOR SAFER CONTACT

Working with dogs that show an established propensity for extrafamilial aggression requires that the counselor-trainer take appropriate precautions to minimize risk of personal injury. Since such aggressive behavior occurs under the influence of territorial incentives and triggers, territorial aggressors are best initially approached away from the home. Approaching a dog that is sensitive and reactive to territorial intrusion by directly entering the house is a very risky practice that should be avoided for several reasons. Not only is the trainer vulnerable to an attack if the owner loses control of the dog, but it is likely that a lasting negative impression will be produced, further reinforcing adverse expectations associated with the arrival of guests and making future training efforts more difficult. First impressions for dogs (and owners) are influential and lasting. In addition to optimizing first impressions and reducing the risk of precipitating an aggressive episode, the gradual approach allows the trainer to perform a variety of procedural probes and tension-reducing procedures to evaluate safely the dog's level of reactivity and to initiate a pattern of interaction conducive to acceptance by the dog. The trainer should mentally rehearse a plan of control or escape if the owner fails to follow instructions or loses control of the dog. Although one should prepare for the unexpected and possess the means and skills to defend oneself against attack and minimize any resulting injuries, mastery is primarily concerned with the acquisition of skills and knowledge to avoid such situations in the first place. The risk of serious attack is an occupational hazard of professional dog training that cannot be entirely prevented; nevertheless, much can be done toward preventing bite-related injuries by taking common-sense precautions, exercising appropriate respect toward the dog, minimizing the use of confrontational procedures, heeding the wisdom of fear, and learning from past mistakes.

The procedure for approaching dogs showing aggression toward strangers and visitors involves several steps. The owner is instructed in advance to have the dog on leash with a slip collar attached in tandem with a muzzle-clamping halter, as appropriate for safety. Instead of directly entering the house, the trainer should knock at the door and walk away from the house while laying a trail of treats dropped at varying distances. The sole of one shoe can be smeared with a small amount of a fragrant odor (e.g., orange, lavender, or chamomile), thereby forming a scented link between the treats. The selected odor can also be put inside a squeaker and dispensed just before tossing the dog a treat. The owner is instructed to direct the dog's

attention to the treats or to pick them up by hand and feed them to the dog. During this introductory phase, the dog should be kept at a safe distance, approximately 10 to 15 feet behind the trainer. Going for a walk is a rewarding activity for most dogs that is made even more so by finding easy treats along the way. As the walk proceeds, the trainer can step off to the side and allow the owner and dog to pass by, and then follow them from behind at a nonthreatening distance. Throughout the process, the trainer and owner should converse, with the owner periodically calling the dog by name, prompting it to sit (if previously trained to do so), and rewarding nonthreatening behavior with affection and treats. The trainer gradually moves in closer, calls the dog's name, uses the squeaker, and tosses the dog a treat. For dogs that remain defensive, the trainer can walk out in front and drop a few more treats for the dog to find. Periodically, the trainer should stop and let the owner and dog pass by, before walking in the opposite direction and signaling the owner to turn and follow along from behind. The approach, follow, and turn procedure is repeated several times. Throughout the process, the owner and trainer should maintain a friendly dialogue.

As the dog's willingness to accept the trainer's presence improves, the trainer can take the leash in hand. With large or potentially dangerous dogs, the trainer can take control of a second leash. The two-leash arrangement provides added control and safety, but should not be used for the sake of gaining an advantage from which to punish the dog. Although the equipment can be effectively used to restrain the dog, if needed to prevent or block an attack, no significant advantage is achieved by punishing a dog while it is restrained or muzzled. The idea is to use the added safety and control of the arrangement to foster trust and help the dog to learn that aggression is not necessary to control the situation. Although some dogs may become reactive as the trainer takes control of the leash, they are easier to calm and typically less aggressive than would be the case if approached or handled while inside the house. The outcome of the introductory process is typically peaceful and serves to provide a useful step toward establishing a working rapport with the dog and the owner. The owner should be encouraged to introduce guests and visiting dogs in a similar way or, at minimum, allow the dog to become familiar with the person before entering the house. The foregoing method of introduction allows the dog to interact away from reactive associations linked to the door. Taking a walk together may allow an outsider to become at least superficially accepted into the family group. During such introductions, the owner and the visitor can perform a number of friendly model/rival exchanges in association with a favorite toy or food item. The visitor is encouraged to toss treats rather than attempt to feed the dog by hand. Feeding a potentially aggressive dog by hand is dangerous and could result in a severe bite, especially at times when the dog is highly excited and distressed. Throughout the introduction and visit in the home, the dog should be appropriately restrained on leash and collar, halter, or muzzle, as needed to prevent an aggressive episode.

Aggressive Barking and Threats Toward Visitors

A complete history of aggressive episodes, including target, location, and severity, should be obtained. Extrafamilial aggression occurring in specific contexts with predictive threats is much more easily treated than is highly generalized or unpredictable aggression. Dogs involved in territorial attacks producing serious injuries should only be cautiously accepted for behavioral training. Similarly, dogs delivering bites unpredictably without warning are by definition untreatable (see *Control and Management of Behavior Problems versus Cure* in Volume 2, Chapter 2). The sorts of judgment needed to assess risks safely and provide appropriate behavioral training come from knowledge-based experience, and only the most knowledgeable and experienced trainers should work with dogs exhibiting extrafamilial aggression.

Dogs showing threats or aggressive behavior during greetings should receive intensive

basic and integrated compliance training focusing on attention, controlled walking, sit-stay, and down-stay modules and routines. The dog's training should be performed throughout the house, yard, and immediate neighborhood, but efforts should be especially focused and intensive around doorways and other territorial frames associated with aggressive arousal (e.g., windows, fence lines, and gates). The starting exercise should be practiced to a high degree of proficiency, with the dog going to the handler's left side without hesitation. The sit-stay routine should be trained to a high degree of reliability up to a 1-minute duration and down-stay up to a 10-minute duration. During the early phases of down-stay training, the handler should frequently return to the dog with rewards, gradually decreasing the reward frequency as the dog's ability to stay improves. The dog's greeting routine should be brought to a high degree of refinement via repeated rehearsal prior to using it in the context of behavior therapy and staging actual greetings with visitors. In addition to practicing the starting exercise and stay training, a quick-sit module should be brought to a high degree of proficiency and practiced under a variety of increasingly difficult conditions. The dog should sit rapidly and remain in the sit position. The training process should set clear limits on impulsive behavior within the context of reward-based training efforts, whereby the foregoing control modules and routines are shaped with food rewards, affection, play, and various everyday rewards (e.g., opportunities to go for a walk). In addition to basic training, PFR training should be performed in locations near doorways (see *Appendix C*). An odor is paired with the induction of relaxation and used during greetings to support social exposure and habituation efforts. Interactive play activities are initiated in association with ringing of the doorbell. Various pieces of equipment, treats, toys, and so forth, should be kept conveniently within reach near the door. A leash should be permanently kept looped over the door handle together with a sign on the door to remind family members not to open the door until the dog is properly restrained or confined.

In some cases involving persistent alarm or threat barking, a remote-activated doorbell can be installed, allowing the handler to activate the sound of the bell while rehearsing the greeting routine. Initially, the bell mechanism may need to be muffled to enable a more gradual exposure and counterconditioning process. Counterconditioning the dog's response to the bell is performed in different parts of the house and at variable times of day. The bell can be used to announce mealtimes and opportunities to go for a walk. Family members can ring the doorbell before entering the house and again as they leave. The combined effect of such conditioning is to integrate new associations with the sudden change associated with the sound of the bell, giving it a broader significance than just announcing the arrival of a visitor. In cases where the dog is highly reactive to the bell, it can be disconnected, or visitors might be encouraged to knock on the door instead. Training dogs that become agitated during greetings to bark on cue may be useful to shift their alarm-barking behavior slowly from conflictive motivations toward a more appetitive incentive. Naturally, this approach is most effective with dogs that have strong appetites. Perhaps the most important training needed to improve control during greetings involves attention training and establishing basic leash control, especially focusing on controlled and slack-leash walking. Orienting/TAT that incorporates periodic positive prediction error (surprise) is a highly effective preliminary strategy for establishing control over excessive barking and reduced impulse control. In cases where the dog becomes highly aroused to the sound of the bell, a family member [familial intermediary (FI)] can go outside and bring the guest inside the house. A rival/model procedure can be used at such times, whereby the guest is given a highly desirable food item or toy by the FI. The guest should show interest and gratitude but return the item to the FI, who in turn gives the item to the dog. Afterward, the guest and FI can exit the house, followed shortly thereafter by the dog and handler. Perhaps the best way for the dog to habituate to the novelty of an unfamiliar visitor is by

going for walks. For highly reactive dogs, such familiarization efforts should be performed in advance of counterconditioning. The familiarization process appears to be largely mediated by habituation. A great deal of behavior therapy is involved in facilitating familiarity on a number of sensory levels. Repeated and noneventful exposure gradually helps to reduce aggressive reactivity in many dogs, but not all.

During the enactment of staged greetings, aggressive dogs should be kept on a muzzle-type halter hooked via a closed-loop leash to a limited-slip or prong collar. In the case of owners uncertain of their ability to control the dog, the dog should be muzzled or crated during greetings. The dog can also be kept on the same leash-and-collar arrangement while outdoors (see *Halter Collars* in Chapter 1). Dogs expressing a rigid watchdog attitude or an established history of serious aggression toward visitors are best kept on leash and muzzle or crated during visits.

Ideally, in anticipation of a visit, the owner should practice ringing the doorbell and pairing the event with a treat tossed against the door and repeatedly rehearsing the dog's role, using both reward-based and directive means to establish reliable control. Whenever possible, asking visitors to call a few minutes before their arrival can help time such preliminary preparation and training. In the case of highly reactive dogs, the owner and dog can meet the visitor outdoors and take a walk. At such times, the visitor is instructed to walk 15 or 20 feet out in front, and the dog is walked in the controlled position on the left side. Pulling is consistently countered with appropriate leash prompts and directive control efforts. The visitor can be instructed to fade back by slowing down and staying safely to the left or right of the owner and then to go back in front again. The visitor can also be instructed to turn about and approach the owner and dog frontally following a wide arc first away from them and then toward them. Gradually, more direct frontal approaches can be practiced. The trainer usually plays the visitor's role, at least initially. If the dog shows signs of habituating, a greeting at the door may be staged. As the doorbell rings, the handler tosses a highly valued treat against the door, taking advantage of the click as it glances off the door, and draws the dog's attention to it. The idea is to link the doorbell with surprise of sufficient strength to antagonize aggression-instigating associations established with the bell sound. The dog is prompted away from the door and drawn to the handler's left side (starting exercise), where it is prompted to sit. In some cases, a large and highly attractive food item is left outside for the visitor to find and give to the dog. As the item is placed on the floor and the handler releases the dog to take it, the guest should not attempt to directly interact with the dog. Subsequent rewards are delivered in accordance with a differential reinforcement of other behavior (DRO) schedule, whereby the dog is given a food reward of variable value after a brief period, regardless of ongoing behavior, provided that no threats or barking occur during the DRO period. When the DRO criterion is satisfied, a smooch or squeak previously conditioned in the context of orienting/TAT is delivered to cause the dog to orient, followed by a click or "Good" as the dog makes eye contact with the handler. A flick of the right hand is used to deliver the reward. If the dog fails to orient within a 1-second limited-hold period, the reward is lost and the dog is prompted to turn about by taking two or three steps back, whereupon it is guided into the starting position and rewarded. As the dog is focused, it is released and the DRO schedule is reset.

During this phase of training, a pattern of control and reward is established that encourages more cooperative behavior and a perception of safety. The repeated activation of an orienting response appears to produce a significant calming effect (see *Autonomic Arousal, Heart Rate, Aggression* in Chapter 6). The handler should give the dog treats until it begins to relax, whereupon the guest is invited to make the squeak or smooch sound as the handler continues to deliver the click and food rewards, gradually encouraging the dog to make eye contact. Eventually, the guest is given treats to toss on the floor for the dog to take. After brief preliminary training, most dogs can rapidly learn to accept the presence of a visitor on limited terms. However, some

dogs may persist in threat barking and other displays that strongly recommend inhibitory measures for control. During exposure procedures, any aggressive lunging is countered with a directive leash prompt with the dog taken to time-out (TO). The combined punitive and dearousing effects of TO can be highly useful for controlling such agonistic excesses (see *Time-out* in Chapter 7). TO is initiated with a firm tone of voice ("Enough, Time-out"), whereupon the dog is abruptly hauled through the front door. The door is then shut on the leash, giving the dog just enough room to stand and sit on the other side. Provided that the dog is not barking, after 30 seconds it is brought back inside with a squeak, orienting response, click, and food reward. A food reward is delivered according to a brief DRO schedule (3 to 5 seconds), provided that the dog does not show threatening behavior. If the dog begins to bark again, the TO is repeated in a similar way, and additional TOs are applied as needed. Repeated TOs appear to mobilize passive modal strategies, which can be complemented by using a modified DRO schedule as previously described. Not only do such rewards help to reinforce prosocial behavior, they also serve to produce a calming effect by evoking emotional arousal incompatible with anger and fear. Most importantly, however, surprise generates active modal strategies in association with the activation of the seeking system—arousal and behavior incompatible with an aversion for social novelty. Whenever possible, massed trials are staged at the door until the dog appears to welcome the entry of the guest (e.g., the trainer). The preliminary exposure and habituation process combined with staged greetings helps to process the integration of scripted roles and social rituals in accordance with safe expectations, thereby building a foundation of trust and an anchor of continuity extending to future encounters with the same people or other unfamiliar people visiting the house.

A cycle of PFR training can also be performed in the presence of a visitor, but usually only after preliminary control has been established. Before attempting to perform the PFR procedure in the presence of a visitor, the dog should receive several cycles of PFR training and olfactory-signature conditioning (see *Appendix C*). After staging a greeting, as previously described, the guest is brought into the house and situated at a nonintrusive distance away from the dog and instructed to inch forward slightly at each step of the PFR cycle. The gradual approach is continued until the dog is in the lateral-control position. The visitor should not continue the gradual approach if it disturbs the dog and should not come closer than 6 feet of the dog. Any efforts by the dog to get up should be blocked and the PFR process resumed. A previously conditioned dilute odor (olfactory signature) can be used to initiate the massage cycle to facilitate the relaxation response. Each step in the cycle should produce a relaxation response before proceeding to the next. If necessary, the dog can be muzzled during the massage, but at minimum it should be kept on a muzzle-clamping halter attached in a closed-loop fashion to a limited-slip collar (see *Halter Collars* in Chapter 1). Before the dog is released from the last step of the PFR procedure, the visitor is instructed to move back slowly to a safe distance. When the dog is released, the visitor is instructed to make a smooch sound, whereupon the handler should quickly click, reward the dog, and then continue to give variable food rewards on a DRO schedule, providing the visitor with treats to toss (not give) to the dog. The olfactory signature can be dispensed from a scented squeaker, a compressed-air pump, or by other nonobtrusive means. For example, a tissue can be scented and placed in the handler's pocket. When needed, the tissue can be rubbed between the fingers and the odor presented to the dog. The scent can also be passively delivered by putting a small amount of it on the doorknob or entry mat. Another passive method used to transfer the scent is by handshake. The goal of the conditioned odor is to modulate reactive emotional arousal and make the dog more receptive to social engagement and calming efforts.

Precautions in the management of potentially aggressive dogs should lean heavily on the side of safety to fully protect the guest from an attack, as well as to protect the dog from the consequences of biting. Again,

depending on risk and circumstances, the dog may need to be muzzled, confined in a crate, or locked in a bedroom. If restrained in a bedroom, the door must be locked. Visitors have been attacked as the result of accidentally entering a bedroom while searching for a bathroom, for example. Finally, great care should be taken when releasing a dog from such confinement before the visitor has left the home. Many dogs after a period of restraint or confinement can lull owners into believing that they have accepted a visitor's presence. Instead, upon being released from confinement, such dogs may simply trot straight to the visitor and without hesitation attack them. Dogs that have bitten or attempted to bite visitors in the past should not be permitted to take food from a guest's hand, even though it may appear safe to do so. In the early stages of the training process, the guest should be discouraged from making eye contact with the dog; however, once some trust has been gained, progressively more natural social exchanges can be explored in association with orienting and attention training. The dog should be kept on leash and maintained under close control during the entire visit, perhaps kept in a down-stay at the handler's side and provided with periodic massage to support a relaxation response.

An alternative to crate confinement or isolation is the tie-out station, which consists of a length of quarter-inch nylon rope or a vinyl-coated steel cable for dogs at risk of chewing through the line. The line is fitted with a bolt-swivel snap and securely attached to an eyebolt fastened to a wooden beam in the wall. The length of the tie-out cable should not exceed the length of the dog's body plus a half. The tie-out location should be situated in such a way that there is no risk of the visitor coming into too close proximity with the dog. While on the tie-out, the dog should also be kept on leash, with the handler applying appropriate leash prompts to prevent straining, lunging, or rearing up. A tie-out arrangement is useful with particularly aggressive dogs. The tie-out station also gives the handler more freedom to handle the various training paraphernalia without worrying about losing control of the dog. In some cases, an active-control line can be used in combination with a tie-out. The active-control line enables the trainer to exert directive control over the dog while at the same time giving it more freedom to move about. An active-control line is a good compromise between the secure restraint of the tie-out station and the reduced control provided by a leash alone.

As previously mentioned, some extrafamilial aggressors are particularly dangerous at times when guests get up to move around the house or when preparing to leave. Many people have been seriously bitten while reaching down to offer the dog an unwelcome farewell pet. Others have been bitten as they stop petting and say "Good-bye" to the owner. The gradual appearance of acceptance shown by a dog toward a guest during a visit with lots of rewards may lead the owner into a false estimation of the risk. Since highly impulsive dogs (rigid watchdog type) may react aggressively to the increased activity and excitement associated with departures, at such times the dog can be maintained in the starting position or prompted to maintain a sit-stay or down-stay as the visitor gets up and prepares to leave the house. This procedure can be repeated in massed trials, so that the guest getting up comes to be associatively linked with the sitting or lying-down response. In some cases, a PFR cycle can be initiated to precede the guest's getting up and preparing to leave the house and continued a minute or so after the guest has left the house. During PFR training, the dog should be appropriately restrained on leash by means of a muzzle-clamping halter or muzzle, as necessary to ensure safety. Otherwise, the handler should restrain the dog and take appropriate precautions as the visitor prepares to leave the house. As the visitor steps through the doorway, he or she can toss the dog a highly valued food item or toy before closing the door. Careful management, restraint, and safe exposure are crucial for the successful control of such problems.

Aggressive Barking, Lunging, and Chasing

On walks, many precautions need to be taken to head off problems. Both children and

adults enjoy meeting and petting strange dogs on the street. Some extrafamilial aggressors can be surprisingly tolerant of social contact when away from home, whereas others may be more aggressive or unpredictable toward people approaching them when in unfamiliar places. Even with dogs that have a history of aggression toward visitors but appear to be friendly under such circumstances away from home, a difficult-to-assess risk may be present that advises against allowing the dog to have casual contact with the public. As a result, the handler should forewarn anyone attempting to approach the dog about the potential danger and even physically block contact, if necessary, especially if the dog is not wearing a protective muzzle. A muzzle-clamping halter does not protect against such close-quarter attacks and may actually worsen the severity of the bite by causing the dog's jaws to clamp down and hold as the dog is yanked back or the victim attempts to pull away. Many extrafamilial aggressors are particularly reactive in the car, and care should be taken to keep windows rolled up to prevent foolhardy fingers from being injured or lost. Dogs that threaten or lunge at passersby need to be handled assertively to discourage such behavior in the future. Consequently, it is critical that dogs exhibiting such problems learn to walk on leash without pulling. The inhibitory control established in the context of leash training has a generally beneficial effect on a dog's ability to control reactive behavior in response to social and nonsocial change.

Fast-moving objects, especially rapidly accelerating ones in the dog's immediate vicinity, may stimulate a chase-and-grab sequence. Running children, bicyclists, or joggers suddenly appearing and moving rapidly through the dog's home space or along a driveway or property line may instigate intense aggressive arousal in certain dogs. The acquisition of a reactive response to stimuli combining novelty, sudden change, and rapid movement may be highly prepared in predisposed dogs and organized at an early age. Puppies showing signs of reactive behavior in response to the approach of strangers or sudden change should be gradually exposed to provoking stimuli in order to promote habituation, to develop new associations, and to improve impulse control via appropriate control efforts. Many dogs appear to enjoy the invigoration and control associated with the chase-and-threat sequence (see *Drive Systems, Aggression, and Behavior Problems* in Chapter 6). Less confident dogs may be emboldened under the influence of handler reassurance, food, and forward movement. In addition, aggressive threats may be reinforced by a perception that they succeed. Even in cases where the target is not actually influenced by the dog's threats, it may appear from the dog's perspective that its threats caused the intruder to go away; passersby may seem to flee in response to the dog's barking and threats. As the result of barking and running fence lines in response to the approach of passersby, such dogs may become progressively frustrated and annoyed. If they finally succeed in breaking through the barrier or the target attempts to approach them, a serious attack may follow.

The allure of chasing moving objects can be so potent that dogs will often continue to engage in the behavior even after being hit and seriously injured. One particular dog comes to mind that had developed the peculiar habit of chasing and biting the tires of service trucks on a university campus. While lunging and poking around a rear tire, he managed to get his head stuck under the wheel. The dog suffered multiple facial fractures as his head was pushed into soft ground that probably prevented more severe, or fatal, injuries. The dog remained conscious, presumably fully aware of the entire ordeal, and fully recovered, but to the chagrin and amazement of the owner, almost as soon as the dog was well enough to play on the campus lot again, he resumed the same pattern of chasing and worrying the service vehicles that nearly killed him a few weeks before. The dog's passion in life was focused on barking and biting at the tires of slow-moving vehicles. Such dogs require preventive management, alternative outlets, intensive attention therapy, leash training, halt-stay and recall training, and inhibitory conditioning. Although significant progress can be obtained via reward-based training and play therapy, the competing reward associated with the periodic opportu-

nity to chase may be potent enough to maintain the problem behavior. When performed in the context of reward-based training, electronic training can be highly effective in controlling such problems (see *Electrical Stimulation and Chasing Behavior* in Chapter 9).

When in contact with the public, dogs with an established propensity to threaten or bite people should be appropriately restrained by a muzzle or a muzzle-type halter. Since such dogs can easily back out of certain halter designs if they are put on too loosely, the halter should be hooked in tandem with an oversized slip collar (see *Conventional Slip Collars* in Chapter 1) or used in combination with a limited-slip or prong collar via a closed-loop or two-leash arrangement. The slip collar provides a source of added security and backup control if the halter fails. For example, dogs can escape by struggling vigorously against a halter and backing out of it. These canine escape artists can shift the muzzle loop forward by pulling against the leash and sharply wiggling in such a way to cause the loop to slip over the nose, thereby making the halter come off their head. A dog can also break free when an owner nervously attempts to hold the dog back by grabbing the neck strap of the halter and in the process inadvertently squeezes the side-release buckle, releasing the dog. Flimsy plastic buckles should be replaced with metal fasteners. Occasionally, a collar may come apart due to defective sewing or hardware; consequently, every new halter or collar should be carefully inspected and tested for strength before it is used. The author once found that a brand new halter was held together at a critical juncture by only two loose threads. The halter was being fitted on a large and extremely aggressive dog—the extra time spent to inspect the halter narrowly averted disaster. Finally, moleskin can be attached to the underside of the muzzle loop to prevent chaffing and friction sores in the case of highly reactive dogs prone to struggle against the halter. To avoid these problems, the halter needs to be properly fitted and introduced. Unfortunately, novice owners with aggressive or reactive dogs may unwisely attempt to use such devices without hands-on instruction appropriate to the dog's individual needs—a formula for a potential disaster (see *Opening the Training Space*).

Dogs exhibiting an established pattern of extrafamilial aggression away from home should receive thorough orienting/TAT, intensive basic obedience training, graduated interactive exposure with response blocking, and inhibitory conditioning, aimed at enhancing attention and impulse control. Preliminary training should include *reliable* leash-control and stay behaviors. Training a dog to orient away from a target and to make eye contact or to sit or lie down without hesitation on signal and to stay there until released are essential training objectives. The dog gradually learns to cope with the approach of a target by increasing impulse control and turning its attention toward the handler. Interactive exposure with response blocking and reward of behavior incompatible with the chase or threat sequence may help to reduce reactive arousal contributing to the behavior (see *Social Fears and Inhibitions* in Chapter 3). Response blocking or diversion and differential reinforcement of other (DRO) or incompatible (DRI) behavior offers many potential benefits once adequate inhibitory control over impulsivity is in place. Without opening a viable training space via preliminary inhibitory conditioning, most reward-based behavior-therapy efforts are unlikely to succeed and might actually make matters significantly worse. To proceed efficiently with interactive exposure procedures, all evocative situations need to be identified and ranked so that a hierarchy of exposure stimuli is obtained, ranging from least evocative to most evocative. For example, dogs that chase cars might first be exposed to a parked car and then to a slow-moving car, a moving and stopping car, a normally moving car, and so forth. At each stage, barking and lunging behaviors are interrupted or blocked by means of a stop-change or all-stop inhibitory procedure, followed by appropriate reward (e.g., petting and massage) as the dog defers to the limit set on its impulsive actions. In addition to DRO/DRI training using food, ball play can often be introduced in such situations as a substitute source of stimulation and reward. From behind the safety of a

fence, ball tug and fetch and flying-disc play offer the dog a substitute outlet to chase and grab, as the impulse to chase forbidden things is suppressed.

A solid recall and halt-stay response should be established on leash and long line and honed to a high level of proficiency. A long line with a limited-slip collar tied into it can be highly useful for establishing an all-stop response. The long line requires skill to use safely and effectively (see *Leash and Long Line* and sections on stay and recall training in Chapter 1). Preliminary training (e.g., attention, following, recall, and halt-stay) and practice with the long line is begun in a fenced backyard or similar area. When using the long line to discourage impulsive charging, a length of rope is laid out and stepped on firmly at a point that gives the dog enough slack to generate a running speed and momentum that will generate a significant and lasting impression as it is brought to a dead halt. The length of rope set off for the procedure is determined by the specific needs of the dog and should be adjusted to prevent excessive or unnecessary force. A temporary handle is tied into the long line approximately 6 feet beyond the point selected and held with both hands as previously described for holding the leash in Chapter 1. The long line is held as a backup and to turn the dog about or prompt it to come, if necessary. The halt-stay procedure is performed with the dog on leash and long line. Once an impulsive response reaches the point of no return (all-go response) and slips out of inhibitory control, directive or saccadic prompts of sufficient force to counter the dog's forward momentum and turn it about are frequently necessary to regain control (all-stop response). As the dog pulls toward the target, the leash is dropped and the trainer shouts firmly "Stay!" or "Stop!" and braces by shifting weight over the foot standing on the long line and firmly grips the line with both hands. As the dog is brought to an abrupt halt, the trainer approaches the dog or calls it back and, after a brief recovery period, the dog is again exposed to the target with attention and DRO/DRI training. Most dogs show a marked all-stop response to the vocal countermand after one to three exposures to the foregoing procedure. Additional control over the all-stop response can be established by means of practice with throwaway objects (see *Stay Training* in Chapter 1).

In addition to all-stop training (dead halt and stay), stop-change and go/no-go inhibitory training is intensively practiced. The orienting response is repeatedly bridged and rewarded with food to capture and focus the dog's attention on the trainer and to evoke an appetitive establishing operation. As the target is spotted at a nonprovocative distance away, the orienting stimulus is delivered, and a hand and vocal signal is used to prompt the dog to hold a stand or sit. Any efforts made by the dog to move forward or to get up while sitting are preemptively countermanded by appropriate vocal, physical, or leash prompts. As the dog begins to sit, the bridging stimulus (click) is delivered and followed by a food reward of variable value together with relaxing petting and massage aimed at calming and soothing the dog. The dog is periodically called by name and/or a smooch or tongue click sound to make eye contact and is rewarded. So long as the dog orients and makes brief eye contact, a food reward is delivered. If the dog fails to orient and make eye contact or becomes agitated, it is turned about and moved away from the target before being turned around at a less provocative distance for the procedure to be repeated. As the dog's tolerance for contact improves, down-stay and PFR training (e.g., collar, stand, sit, and down controls) is introduced to enhance inhibitory control further.

Effective counterconditioning depends on gradual, nonthreatening exposure to unfamiliar places and provocative target stimuli in combination with appetitive and emotional stimulation (e.g., food, touch, and play) that is incompatible with aggression and fear. The counterconditioning process moves from the least provocative to the most provocative situation. A variety of motivational, contextual, and proximity factors impinge on the efficacy of counterconditioning efforts (see *Stimulus Dimensions Influencing Fearful Arousal* in Chapter 3). Several counterconditioning variations are used, depending on the dog and

problem. The least provocative technique involves walking the dog toward the target and having the dog sit every few steps. A more provocative variation involves having the dog sit and stay as the target gradually moves toward the dog. Here, the target takes several steps toward the dog and stops, whereupon the handler provides the dog with appropriate appetitive or tactile stimulation to offset aversive arousal. In either case, if the dog becomes overly aroused, it is abruptly turned away from the target and walked back to a less provocative distance and the process started over again. Another method involves having the dog follow the target person, who is instructed to drop treats every few feet while moving away from the dog. This procedure can be modified to initiate a searching game, whereby the dog is encouraged to follow a trail of treats laid down by the unfamiliar person. In the beginning of the trail, treats are laid down evenly and frequently (e.g., every 10 feet), but gradually the trail of treats is more randomly spaced requiring that the dog search for clues, including the person's body odor or an odor applied to the person's shoes. Changing the size, frequency, or type of food laid on the track can generate cortical reward and facilitate the process. The combination of the olfactory incentive system, forward movement, and seeking activity may exert a positive effect on the dog's response to the signature odor of the person, perhaps facilitating social familiarity and counterconditioning efforts. Whatever method is used, the objective is gradually to replace reactive arousal elicited by the approach of strangers or persons not belonging to the household with appetitive anticipatory arousal and positive social expectancies conducive to social attraction and friendly behavior. Other variations used during graduated exposure include the approach of groups, situations involving loud noises or boisterous activity, exposure at different times of day (some dogs appear to be more aggressive at night), and varying the speed and naturalness (oddity factor) of the approaching target. Another possibility involves having the target walk back and forth on the horizon line, forming an arc that progressively opens toward the dog, causing the target to come closer and then recede. On succeeding trials, the curve of arc becomes increasing steep as the distance traveled on the horizon line is narrowed. Each variation of exposure to change and novelty should be arranged along a continuum of evocativeness to prevent reactive responses.

Dogs that become reactive during exposure procedures can be dearoused by means of TO. Ideally, the outdoor TO is performed at a tie-out station set up in the open or behind a blind. The tie-out line is wrapped at least twice around a sturdy post and then fixed in place with a carabiner hooked into the handle and snapped onto the line. The tie-out line is positioned on the post to give the dog enough room to stand comfortably or to sit but not lie down. A bolt-swivel snap is used to fasten the tie-out line to the dog's collar. A blind is constructed from two 5-foot by 1-inch PCV tubes that are cut at a sharp angle so that they can be easily pushed or pounded into the ground. For a medium-sized dog, a piece of light cloth material is cut into a 4-foot by 7-foot rectangle, and both ends are folded over and sewn (or stapled) into sleeves large enough for the support poles to be inserted. A center post can be inserted to pull the blind and form an inverted V shape. The blind is rolled up on one of the support poles, making it easy to unfurl and set up. During time-out, the trainer sits in front of the blind while holding a leash attached to a muzzle-clamping halter. In addition to TO, the blind can be very useful for controlling and varying exposures to the target during counterconditioning.

The TO procedure is initiated by saying "Enough, time-out" and then assertively hauling the dog to tie-out post. After 30 to 60 seconds or when the dog has been quiet for at least 10 seconds, the trainer signals approval ("Good boy/girl") and returns to the dog, releases it, and initiates attention and DRO/DRI training at a previously nonprovocative distance from the target. Additional TOs are repeated as needed to control arousal levels and discourage overt aggression. Under conditions that allow it, the TO procedure can include a walk-away consequence, whereby the trainer leaves the dog and waits in a concealed location. Persistent barking

excesses associated with TO can be discouraged by means of a leash attached to a muzzle-clamping halter or by pairing an all-stop vocal signal (e.g., "Enough") with a conditioned odor and compressed-air startle or the sound of a shaker can delivered from behind the dog. As the barking ceases, the trainer returns to the dog and initiates attention and DRO/DRI training to maintain quiet behavior. Bark-contingent muzzling may be useful in some cases of persistent barking, but long periods of muzzling should be avoided, especially in warm weather when unimpeded panting is needed for thermoregulation. In refractory cases, a remote-activated training collar can be effectively used to facilitate the rapid inhibition of barking behavior.

PART 2: INTRASPECIFIC AGGRESSION

With the exception of certain breeds developed for an exaggerated propensity to fight, the dog's domestication has generally resulted in an elevation of the reactive thresholds controlling intraspecific flight-or-fight behavior while selecting for traits conducive to social affiliation and play. Unlike the animosity typically shown by wolves toward unfamiliar conspecifics, the majority of dogs are far more likely to exhibit friendly interest and affiliative behavior toward unfamiliar dogs. Aggression between dogs is under the motivational influence of a variety of social factors (e.g., relative familiarity, playfulness, and tolerance for close interaction and contact) and emotional tensions (e.g., fear, anger, frustration, and irritability). When functioning properly, ritualized agonistic exchanges and transactions may serve to reduce overt fighting; however, as the result of genetic predisposition, developmental stress, socialization deficits, or traumatic learning (e.g., being attacked by another dog), a dog's ability to send, receive, or reciprocate agonistic signals appropriately may be disrupted.

HIERARCHY, TERRITORY, AND THE REGULATION OF AGGRESSION

Among wolves, cooperative order within the family/pack appears to develop in the context of an emergent leader-follower bond established in association with a natural tendency for the young to follow the breeding pair. Social dominance and leadership are expressed in a division of labor between the male and female, whereby the male defends the living space against intruders and leads hunting activity aimed at procuring food for the mother and offspring, and the female defends the den and immediate core surroundings and leads activity dedicated to offspring care and protection (Mech, 1999). Active submission and greeting behavior appears to develop in association with food begging, whereas passive-submission training carried out by adults appears to constrain obtrusive behavior. Regurgitation and the cooperative provision of other stores of food by the wolf parents sets the stage for sibling social differentiation (sibling dominance hierarchy) based on their relative abilities to compete successfully for limited food rations. With the introduction of solid food and an increasing unwillingness of the mother wolf to nurse, a process of weaning slowly transitions the pup from a completely dependent status to a progressively independent relation with the parents. Wolf behavioral ontogeny transitions through several developmental stages from complete vulnerability and dependency to a state of self-reliance, independence, and dispersal to form a separate family and home range.

Among wolves, dominance is most predominantly correlated with the procurement, ownership, and distribution of food, scent-marking behavior, and the defense of territory. Territorial claims are secured by means of residency, advertisement (e.g., scent marking and vocalization), mutual recognition and avoidance of the territorial claims of others, and the capacity to eject intruders (see *How Territory Is Established and Defended* in Volume 2, Chapter 7). Scent marking is the prerogative of the breeding pair or more rarely subordinates ascending in rank (Mech, 1999; Peterson et al., 2002). The breeding pair often engages in double marking, especially during the breeding season (Asa et al., 1985; Mertl-Millhollen, 1986). The double-marking ritual may help to establish a strong pair bond prior to estrus. Coyotes living in packs exhibit a

similar pattern of scent-marking behavior (Gese and Ruff, 1997). Scent marking appears to be well suited for the demarcation of territorial boundaries. Odor signals do not depend on the immediate presence of the signaler to be effective, they can be deposited in small amounts over a large area, and they persist for a long time after being deposited. The distribution of scent marks provides a spatial and temporal record of the signaler's past activities and likely whereabouts, thus improving the ability of neighboring conspecifics to avoid contact and potential animosities (Peters and Mech, 1975). At closer distances, vocal indicators of presence (howling) (Harrington and Mech, 1979) and barking threats (Mech, 2000) may advertise residency and warn intruders of trespass. Actual attacks on conspecific intruders are initiated and led by the breeding male (Mech, 1970).

Whether dogs use urine to demarcate territory remains controversial (see *Urine Marking and Territory* in Volume 2, Chapter 7) and, although a communication function appears to be involved (Bekoff, 1979a and b), the precise nature of the message and its function remains enigmatic. Bekoff (2001a) collected data regarding a dog's sniffing and urine-marking habits over 5 years. The dog marked somewhat more frequently over the urine of other males than females and only infrequently urinated over its own urine spots. These findings support previous work indicating that the trigger for urine marking is the scent of another male or female dog (see *Eliminatory Behavior* in Volume 2, Chapter 9). Pal (2003) has reported that free-ranging dogs are more likely to mark after observing another dog mark, suggesting that the leg-lifting action may perform a visual releaser function. Raised-leg displays (RLDs) (leg lifting without urinating) were found to occur frequently after competitive interactions involving territory and courtship, indicating that such behavior might serve an agonistic function. Similarly, Bekoff (1979b) reported that RLDs occurred most frequently while another dog was present. Among free-ranging dogs, urine marking is more frequent during the breeding season in areas associated with courtship and territorial boundaries (Pal, 2003). Also, dog mothers scent mark more frequently near the den site, perhaps with the intent of warding off intruders, but there is little evidence that dogs avoid areas scented with urine. Increased scent marking by male dogs appears to occur in association with the trespass of territorial boundaries and in response to finding unfamiliar objects within the territory. High-ranking male dogs appear to mark over urine deposits left by estrus females, suggesting to Pal that such marking may perform an ownership function. Pal also observed that dogs urinated on garbage and food left over after eating, and speculated that such marking might help dogs to find the food when they returned to the area. Pal refers to the work of Henry (1977) in support of the foregoing hypothesis. Henry, however, demonstrated that foxes urinated on inedible food items and substrates scented with traces of food so that such items and locations could be ignored when come upon in the future, thereby making scavenging activities more efficient. A similar *bookkeeping* function of urine marking has been reported in coyotes and wolves, providing further support for Henry's bookkeeping hypothesis; that is, cache marking is probably performed by canids and other species (Devenport et al., 1999) to help them to discriminate the absence of edible food (Harrington, 1981; Gese and Ruff, 1997). In the case of wolves, Harrington observed that, after emptying a cache, urine was deposited into the hole presumably to mark the cache as empty.

Dogs take an avid interest in the urine deposits of females, regardless of their reproductive status, suggesting the possibility that such investigation and urine marking may serve a similar reproductive bookkeeping function. After observing a female urinate, the intact male often goes to the spot, investigates the urine with its nose or licks it, and then deposits a splash of urine nearby or directly on it. According to the bookkeeping hypothesis, the dog's interest in the female's urine may serve the purpose of collecting and appraising olfactory and pheromone information indicative of her reproductive status. The increased interest shown by males toward the urine of females in estrus may also be organized to

detect pheromone signals (e.g., methyl *p*-hydroxybenzoate) that are shed in association with the onset of ovulation (see *Vomeronasal Organ* in Volume 1, Chapter 4). The subsequent scent mark may not denote possession, but rather serve to let the marker know that the spot had been previously checked. Dunbar and Buehler (1980) have suggested that dogs might urinate over female scent marks in order disguise or mask them, ostensibly with the goal of throwing other males off the female's scent. Urine marking by male dogs preceding a fight may transmit identifying olfactory information that is associatively linked with the outcome of the agonistic encounter. According to this hypothesis, urine deposited by the winner may not only serve to weakly conceal the female's scent, as proposed by Dunbar and Buehler, but, more significantly, the winner's urine may evoke active avoidance of marked spots, thereby deterring closer scrutiny and discovery of the female's reproductive status.

Another plausible function of urine marking is related to *securing* an unfamiliar place or object by rendering it familiar with the dog's urine scent (Kleiman, 1966) (see *Behavioral Effects of Domestication* in Volume 1, Chapter 1). According to this hypothesis, urine deposits may at least indicate to a dog that it is on ground that had been safe in the past. Urine deposits may also provide information about the shared use of an area (Eisenberg and Kleiman, 1972), performing something akin to a public bulletin-board function (see *Urine Marking* in Volume 2, Chapter 9). Observing the urine marking of other dogs may prompt close investigation of the spot, followed by double marking, a ritual that frequently anticipates sexual play and the integration of friendly relations between male dogs not sharing the same household. In some cases, however, dogs may urinate in close association with hostile arousal and intent, perhaps performing the display as part of a preliminary ritual in anticipation of a fight (Ralls, 1971), whereas others may be more likely to mark under the influence of conflictive arousal and uncertainty. In both cases, urine marking might represent a nerve-steadying ritual, engendering confidence and place security, and briefly killing time before deciding on a course of action. Urine marking may also serve a cutoff function, occurring subsequent to the exchange of intense threats that are broken off before escalating into an actual fight. For example, Lorenz (1955) describes an agonistic encounter between two evenly matched dogs that concluded with the competitors slowly disengaging and saving face by mutually standing down and walking away in opposite directions, whereupon both eyed the other and simultaneously squirted urine against separate posts and left the scene without further incident. Ground scratching frequently follows urine marking. Bekoff (1979a) has observed that dogs performing the display may be avoided by other dogs during the activity and for a short time afterward, but they do not subsequently avoid the urine deposit and scratch marks.

The ancient phylogenetic origins of urine marking have probably resulted in a number of polymorphisms influencing the form and function of the rituals and displays associated with it. The significance of urine marking, like that of barking, probably depends on the survival mode active at the time and the context in which it occurs. A genetic factor appears to affect the urinating behavior of purebred and mixed-breed dogs, with purebred male dogs urinating more frequently than mixed-breed counterparts (Reid et al., 1984). The evident hypertrophy of marking behavior in purebred dogs may be a secondary characteristic resulting from the selection of dogs that readily and enthusiastically perform siring functions—a highly desirable and valuable trait in stud dogs. Purebred dogs are also most frequently implicated in household fighting—behavior that is sometimes also associated with household marking problems (Sherman et al. 1996). Sherman and colleagues interpret urinating/marking as a way that such dogs assert dominance and mark territorial boundaries, suggesting that such dogs should be prevented from performing the "alpha wolf behavior of marking territorial boundaries during walks" (107). Aside from practical considerations regarding how one might achieve such an intrusive prohibition without risk to desirable urination habits and

various other potential problems associated with the proposed treatment procedure (see *Urine Marking and Intermale Aggression* in Volume 2, Chapter 7), the underlying assumption that urine marking serves a territorial function in dogs remains to be convincingly demonstrated (see *Evidence for a Territorial Function of Urine-marking Behavior* in Volume 2, Chapter 7). The danger of placing undue emphasis on a threat-signaling function of urine marking was a concern of Eisenberg and Kleiman (1972), who admonished researchers to avoid thinking of scent marking as performing a territorial defense function:

> Thus, we must divorce ourselves from considering scent marks as a means of territorial defense; rather, we should think of scent as a means of exchanging information, orienting the movements of individuals, and integrating social and reproductive behavior. (24)

Furthermore, even if urine marking did deter territorial trespass, evidence of avoidance alone would not necessarily support the notion that the marking activity was performed with an agonistic or territorial intent:

> The thesis that scent marking in mammals arose from autonomic responses and evolved into a means of familiarizing the animal with its environment and reassuring it in unknown situations is very useful. It certainly does not exclude the numerous social functions which scent marking has gained during the evolution of the behavior, but it does imply that they evolved secondarily. This thesis also suggests that scent marking is not used as an agonistic display for territorial defense even though the behaviour is effective in maintaining a territory. Its efficiency simply lies in the avoidance responses which are shown by the intruding individual. (Kleiman, 1966:176)

Framing the Concept of Hierarchy and Territory

Wolf Family Life, Hierarchy and Territory, and Feral Dogs

The closely interwoven and complementary functions of hierarchy and territory cannot be arbitrarily separated and studied in isolation without losing significance. Just as the boundaries of a country are defended to protect cultural and political interests as well as economic assets, territory serves multiple social, reproductive, and ecological functions conducive to the viability of the group to survive and reproduce successfully. Among wolves family/pack defense is the prerogative of the breeding pair, with the breeding male leading attacks against territorial intrusions, while the breeding female appears to take the most active role in the defense of the den (Mech, 2000). Governance by hierarchy and territory appears to subserve reproductive goals and family survival functions by promoting the equitable distribution of family resources and by facilitating cooperative hunting and sundry other group activities conducive to reproductive success, group stability, and the survival of offspring (Mech, 1999). The reproductive significance of governance becomes strikingly evident if the breeding male dies. With the loss of the breeding male, subordinate members of the family/pack appear to be much less concerned by the intrusion by outsider males and may rapidly integrate social relations with them. At such times, territorial intolerance and animosities toward outsiders are dramatically relaxed, thereby giving dispersed males an opportunity to enter the home range and fill the vacancy as pack leader (Stahler et al., 2002). The cooperative governance, stable pair bonding, family organization, and cooperative care for offspring shown by wolves are not evident in feral dogs, suggesting the possibility that a functional system of governance by hierarchy and territory may not exist in dogs or is expressed in a significantly variable and modified form. Although a socially integrated group of feral dogs has been observed to show territorial aggression around the edges of shifting core areas where they spend most of their time in close association with food resources, resting and retreat sites, and dens (Boitani et al., 1995), they do not appear to exhibit the coherent social organization that is evident in the governance of the wolf family. Finally, in addition to the social function of territory, territoriality serves a valuable ecological function by spreading competing groups over a geographical region, thereby preventing overhunting and the

depletion of local resources while opening up new areas for exploitation. The territorial separation of small family/pack groups may also serve an important epidemiological function by slowing the spread of contagious disease that might risk decimating larger groups living in close proximity.

Social Attraction and Repulsion, Governance, and Canine Proxemics

Whereas territory moderates conflict by means of physical spacing, hierarchy moderates conflict by means of social spacing. Together, territory and hierarchy form a unified sociospatial complementarity in the regulation of conflict (Figure 8.3). The attraction and repulsion dynamics and sociospatial relations formed while organizing a default hierarchy is referred to as a *social space* (see *Horizontal and Vertical Organization of Social Space* in Volume 2, Chapter 7). Typically, interactive conflict is triggered by dyadic-control vectors converging on some point of common interest that can support only one interactant at a time (e.g., possession of a bone, resting spot, or mate). The mutual agonism and affiliation associated with the formation of sociospatial relations is expressed in attraction-repulsion fields that radiate out from the point of common interest or conflict along a gradient of decreasing conflict and repulsion. *Axipetal forces* consisting of appetitive and social attraction draw the repulsed subordinate back toward the point of common interest and the center of social space, whereas *axifugal forces* consisting of social repulsion produce dispersal dynamics that cause the subordinate to withdraw and stay away. These forces of appetitive and social attraction and repulsion are reflected in canine-proxemic relations (see Hall, 1963 and 1968), affecting the various ways dogs use and regulate close social space and tactile contact in the process of attuning (coregulating) to one another and human companions. Essentially, sociospatial relations are the result of the expansion and contraction of social space in association with the establishment of hierarchy and territory. As such, hierarchy and territory represent the warp and weft of a single cloth of integrated social and environmental regulation referred to as *governance*.

Under circumstances in which a high level of appetitive and social attraction counters the repulsion generated during the establishment of sociospatial relations, the subordinate may be drawn back to offer sincere conciliatory-submission displays, seek acceptance from the dominant, and beg for nurturance and protection. If the dominant possesses sufficient social attraction to accept the subordinate's submissive efforts, collectively referred to as a *voluntary subordination strategy* (VSS), then a cooperative and harmonious relationship may develop between them via the formation of a leader-follower bond and interaction organized in accord with a principle of fairness, the mutual adherence to social codes, and the emergence of pluralistic ascendant and descendant relations. The development of ascendant and descendant relations within a shared social

FIG. 8.3. Attic red-figure vase by Andocides, ca. 510 B.C. Territorial aggression can be significantly escalated by social facilitation. Two dogs aroused by a common target appear to become a third entity in their union of animosity—a transformation reminiscent of the three-headed Cerberus, the monstrous dog guarding the portals to Hades in Greek mythology.

space provides several significant benefits for both the subordinate and the dominant members of the group (see *Unilateral, Bilateral, and Pluralistic Relations*). Whereas submission with attraction toward the dominant appears to generate affection, loyalty, and respect (i.e., secure social attachment), submission without attraction results in social ambivalence (anxiety, resentment, and contempt) in association with an *involuntary subordination strategy* (ISS) and entrapment. Under the influence of social ambivalence and entrapment, conflictive dynamics and tensions infiltrate the social space in the process of mobilizing dispersive dynamics and autoprotective behavior.

The dynamic axipetal and axifugal forces resulting from mutual attraction and repulsion produce a state of social equilibrium and integration (s and p types) or social disequilibrium and dispersal (c and m types). In addition to agonistic tensions, the organization and maintenance of social relationships is subject to stress-related modal switching that requires flexible coping skills and an ability to shift in accord with the activation and deactivation of survival modes. Attraction is a composite force consisting of appetitive and social incentives; as such, social attraction in the absence of appetitive security is not sufficient to maintain secure attachments, just as appetitive gratification in the absence of social affirmation and affection is also insufficient. Under the influence of insecure attachments and a reactive coping style, proxemic relations may become increasingly unstable under the disorganizing influence of social anxiety and contact aversion. Building secure attachments is a central focus of cynopraxic therapy, which places equal emphasis on bond-enhancing training and QOL enhancements—the yin and yang of cynopraxic therapy. Training without QOL enhancements or vice versa is not conducive to the attainment of cynopraxic objectives. The dynamic effects of survival-mode switching on the regulation of social attraction and repulsion represent a potentially valuable area for future study into the relationships between QOL, canine proxemics, and aggression.

Avoidance Learning and Despotic Hierarchies

According to the avoidance model of hierarchy, the establishment of hierarchical relations consists of an *escape phase* and an *avoidance phase*. During the escape phase, the dominant displaces the subordinate by severe threat or the infliction of pain or injury (if necessary) and thereby eliminates the conflict and takes control of the contested resource. The subordinate is doubly punished by the physical pain and injury resulting from the attack and the immediate and perpetual loss of control over the contested resource. Repeated defeat may cause the subordinate to experience increased social anxiety and depressed mood—psychological effects of defeat that may reduce testosterone and growth hormone levels, decrease immune functions, and thereby adversely affect the animal's fitness. Under similar circumstances, at least in the short term, the subordinate will fear and avoid the dominant and the places it occupies. In addition, the subordinate in the future may now respond to threatening intention movements (e.g., piloerection, direct stare, stiff frontal approach, and snarl) as discriminative stimuli controlling avoidance behavior (e.g., turning away and hesitation). Also, behaviors associated with the reduction or termination of attack (e.g., dorsal recumbency) may be used to interrupt the attack sequence. If these avoidance responses are successful, the subordinate may experience some degree of relief and relaxation—emotional sources of intrinsic reward that may support subordinate avoidance and antagonize fear. To the extent that subordinate avoidance responses work in this way, they will tend to promote feelings of safety. The subordinate's heightened responsiveness to the slightest tension in the dominant's gaze may cause the latter to feel securely in control, thereby reinforcing the threat sequence and perhaps reducing the likelihood of an actual attack. Threat gazing may be used to regulate subordinate behavior or prompt retreat, whereas averting eye contact by the subordinate may signal its prompt intent to move in a direction away from the conflictive encounter.

The threat of the dominant is an expression of anger held in check by competent emotional regulation and confidence that the subordinate will not fight back. While the threat display expresses an angry intent to attack held in check, the antithreat display of the subordinate is an antithetical intention movement geared toward immobility or flight that is matched to the perceived strength of the threat. When directed toward a subordinate, the dominant threat elicits fear. In contrast, agonism between two dominant individuals results in rapidly escalating threat exchanges based on mutual anger. In the case of equally dominant dogs, threats are reciprocated by counterthreats measured to accord with the perceived readiness of the other dog to attack until a flash point of no return is reached. Accordingly, threat displays induce anger in the dominant dog receiving them. The agonism between the dominant and subordinate dyad is kept in equilibrium by confirmative transactions consistent with anger/fear expectations formed as the result of past encounters. If the antithreat display given by the subordinate is delayed or insufficient (disconfirmed), the discrepancy between the expected antithreat display and the actual antithreat display may escalate threat tensions, that is, increase fear and anger. Under the influence of elevated anger, the dominant may intensify its threats, causing it to become increasingly angry and, if sufficiently provoked, launch into an attack. Alternatively, the subordinate, recognizing that the antithreat display given not only failed to reduce the threat but, in fact, increased it, may respond to the discrepancy by becoming more fearful, causing it to increase the intensity of the antithreat display, thus making it commensurate to the escalating threat of attack. In both cases, social signaling is exchanged under the modulatory influence of social feedback on control incentives, anger/fear-establishing operations, and prediction-control expectancies. The gestural conversation between the competitors is adjusted in accordance with discrepancies between the size of the threat given and the latency/size of the antithreat display reciprocated. Antithreat displays that match the expectations of the dominant result in a de-escalation of threat tensions, whereas mismatches result in the escalation of threat tensions, perhaps followed by an attack and defeat while reinforcing the dominant-subordinate relationship and increasing the subordinate's future readiness to show antithreat displays when challenged.

Consequent to a successful attack, the dominant is doubly rewarded by the emotional elation of enhanced power and the control established over the contested resource. As the result of similarly successful attacks on other group members, the aggressor systematically consolidates power and exploitative control over the group's resources. Group subordinates may similarly compete among themselves until a hierarchy of power relations is established. As a general rule, more extraverted and fearless (bold) group members tend to dominate and exploit more introverted and fearful (shy) members. As the result of receiving the most attacks from other group members, individuals at the bottom of the nipping order may be most adversely affected physiologically and psychologically by formation of a rigid hierarchy. However, a despotic dominator also stands to lose out and may not ultimately reap the benefit of its power exploits. The power gained by the dominant is won at the cost of bond-enhancing interaction with subordinate group members—a factor that may influence its a ability to function effectively within the group. The increasing success of the dominant to intimidate and exploit other group members promotes social avoidance and the gradual degradation of social attraction and attachments. The loss of social ties with group members may mobilize dispersal dynamics that marginalize the dominant (ostracism) and gradually cause its expulsion from the natal group (see Bekoff, 1977). As a result, the despotic hierarchy appears to be in the long-term advantage of middle-ranking individuals, who can interact on a friendlier basis with one another and thereby form stronger group ties.

Among dogs, submission rituals appear to serve important social modulatory functions that offset the adverse effects of hierarchy formation by helping to decrease social distance and facilitate reconciliation by paradoxically

increasing social attraction in response to dominator threats and attacks. The formation of hierarchy is not merely the outcome of avoidance learning but also involves the molding of social attachments via submission and reconciliation rituals. These affiliative rituals mediate enhanced attachment by establishing exchanges and relations that regulate aversive emotional arousal produced in association with agonistic threats or fights. Consequently, the formation of dominant-subordinate relations in the absence of social attraction, submission, and reconciliation promotes dominant intolerance/irritability or *contact aversion* and subordinate anxiety, resentment, and avoidance. Accordingly, dominants that fail to attract affectionate submission displays or fail to accept and reconcile with subordinates subsequent to agonistic conflicts may weaken social attachments and reduce the ability of the competitors to form social attachments in the future, thereby increasing the risk of setting into motion dispersive tensions. The lowest-ranking member (omega) faces a similar risk of dispersal in situations where social avoidance replaces submission and reconciliation rituals in the process of constructing a nipping order. Whereas all group members may be compelled to avoid the increasingly intolerant and irritable dominant, the omega may be compelled to avoid all other group members and enter into a similar condition of social marginalization but on the opposite end of the hierarchy. As a result of reduced social attraction and affiliation, both the despot and the omega may fail to form social relations conducive to secure attachments. In social situations that bar dispersal, the marginalized dominant and omega may become increasingly irritable, intolerant, and reactive toward interference by other group members.

Unilateral, Bilateral, and Pluralistic Relations

The foregoing inherent limitations affecting the despotic model of governance appear to be addressed by evolution of a pluralistic form of social governance based on the primacy of social attraction, social codes, and fair play. In contrast to the unilateral avoidance relations making up the despotic hierarchy, the pluralistic model of social organization differentiates between unilateral avoidance relations and bilateral ascendant-descendant relations organized in accordance with a principle of fairness. Within a pluralist system, a default hierarchy informs the structure of the relationship, but hierarchy relations do not define the sociospatial and dynamic content of the relationship. In pluralistic systems, dyadic attraction and repulsion dynamics appear to shape social attunement strategies organized to establish stable and harmonious group relations. Whether two dogs fight over a common object of interest depends on default-hierarchy relations, mutual-need tensions, control vectors and incentives, relevant social codes, relative social attraction or repulsion dynamics, and competency to coregulate each other without fighting. Although the more aggressive and dominant member of the dyad might choose to displace the more inhibited and submissive member in accordance with the default hierarchy, such activities require energy and are performed with some degree of risk that the subordinate might fight back, especially in situations involving highly valued items. Such fighting might also result in a loss of interactive contact with the defeated subordinate and increased dispersive tensions. These factors appear to add a component of “politics” to the formation and maintenance of power relations. Consequently, in situations where the subordinate might indicate a strong interest in some resource or activity that might be of only moderate or passing interest to the dominant, relinquishing control to the subordinate may be in the dominant’s best interest.

The emergence of bilateral ascendant and descendant social relations organized in accordance with individual control incentives and the dominant’s consent appears to reduce interactive conflict over resources of little value to the dominant but still leaves open a significant risk for disruptive competition to break out over resources of high value to both dominant and subordinate members. In addition to the formation of rigid hierarchy relations around the point of common interest,

some of these conflict situations may be reduced by mutual adherence to emergent social codes (e.g., rule of first possession). Adherence to social codes and rules of fair play appears to help promote friendly relations, harmony, and trust-based bonding. The safe center of the home or living space is defined by secure social and place attachments mediated by mutual attraction and desire to affiliate (affection) in accordance with social codes, fair play, and trust. The safe center is conducive to social engagement, play, mutual appreciation, and interactive harmony. These social codes acknowledge the rights of other group members to comfort and safety and to own and defend personal space and the objects contained within that space conducive to comfort and safety. Group members often (but not always) respect the rights of first possession, especially as regards highly prized items. Social codes appear to develop in the context of give-and-take negotiations and play fighting. For example, puppies learn early on that if they bite too hard or in the wrong place, the play partner will either quit or attack in retaliation. Puppies lacking sufficient play experiences with other puppies often show poor bite inhibition and reactive incompetence toward other dogs and people in adulthood. Interestingly, most socialized puppies show evidence of code-consistent behavior with respect to the site of playful biting directed toward people. Puppies that avidly and persistently bite hands will often switch to licking if presented with the human face. This shift from biting hands to licking the cheek occurs independently of training and appears to represent a canine polymorphic variation conducive to human-dog affectionate bonding. Other puppies show a highly problematic and persistent pattern of periodically jumping at the face and nipping at the nose or around the eyes, perhaps representing a canine polymorphic variation that impedes human-dog affectionate bonding. Face-licking-type and face-nipping puppies appear to express coping styles associated with social dynamics and tensions that tend toward the integration of voluntary and involuntary subordination strategies, respectively.

In contrast to the despotism, involuntary subordination, and dispersive tensions that develop in the context of unilateral power-dominance relations, social interaction guided by pluralistic ascendant and descendent relations tends to promote flexible social relations and voluntary subordination. Bilateral relations and sharing of group resources facilitate cooperative projects and ventures, whereby leader (ascendant) and follower (descendant) roles are determined in accordance with natural talent and skill to accomplish some group-beneficial objective. For example, among wolves, the mother wolf takes the lead in the care and protection of offspring, whereas the father wolf leads hunting and territorial activities. In practical terms, the notion of a *working dog team* is based on a similar balance of bilateral leadership relations and the functional specialization of cooperative roles based on talent and skill. Each member of the working dog team plays obligatory leader or follower roles depending on the needs of the mission and the practical tasks for which the team has been trained. The performance of mission-consistent tasks is called work but is really disciplined play. The process of training integrates a balanced organization of handler-dog ascendant and descendent relations and roles shaped in conformity with the work performed by the team. The handler needs the dog's olfactory sagacity and skill to locate the hidden object of common interest and must defer to the dog's lead in finding it. The dog needs the handler's guidance to ensure that the work succeeds and concludes in play. Only the trainer knows the practical significance of the mission; for the dog, the mission is aimed at securing a common point of interest that denotes activity success and prompts the handler to initiate a bout of vigorous social affirmation and play. The working dog team works to affirm one another's expectations and to celebrate their mutual success by engaging in play.

Social Attraction, Submission, and Pluralistic Agreements

Social dominance is not always and consistently unilateral, but may involve considerable

variation especially among dogs that share a strong mutual attraction, playfulness, and a common set of secure attachments. Instead of forming a unilateral dominant-subordinate relationship, such familial canine dyads may establish complex ascendant or descendant pluralistic relations with one another, depending on the situation involved, individual-need tensions, and control incentives associated with the resource (see *Unilateral, Bilateral, and Pluralistic Relations*). Most dogs sharing a household appear to integrate bilateral pluralistic relations with respect to access to valued resources and group activities, whether a default-hierarchy relationship between them exists or not. The establishment of bilateral ascendant and descendant relations depends on shared expectations and trust that the other will adhere to a code of play fair. According to the pluralistic hypothesis of social organization between canine familial dyads, the agonism between evenly matched competitors is held in check by pragmatic self-interest and trust-related expectancies mediated by give-and-take exchanges and adherence to a principle of fair play. Highly playful and affectionate young dogs establishing attraction-based dyads appear to form relationships that are primarily of a pluralistic nature, since neither of them are willing or are unable to compel the other to submit. In the absence of a default-hierarchy relationship, such dyads may be at an increased risk of certain competitive problems as they grow into adulthood. The most stable social relationship forms in the context of high levels of social attraction and playfulness in which one partner compels the other one, at least once, to yield submission and in turn accepts the submission of the subordinate, reconciles, and forms a harmonious default hierarchy around which to integrate fluid and pluralistic relations.

Interactive conflict around points of common interest varies in accordance with individual-need tensions, control vectors, and control incentives. For some dogs, getting close proximity and attention from the handler is a resource worth seeking, whereas others may be more likely to seek food or other tangible items that they prize. As a result of such motivational differences, control interests converging on social and appetitive resources in the home produce different competitive tensions and potential for striking up aggressive conflict. Pluralistic dynamics between dogs shift depending on the value placed on the convergent point of interest, with one dog taking an ascendant priority of access relative to the other, depending on motivational differences and incentives to control the object or situation. When conflicts emerge in such situations, it is not so much about asserting or testing dominance as it is about laying claim to valued resources and transmitting information about the value that particular resource holds for them. Whereas a resource possessing a high value is reflected in a willingness to invest a significant amount of energy and to take risks to secure it, less valued resources tend to attract a minimal investment of energy or risk taking. In conflict situations over valued resources, dyad members bring different energy-investing and risk-taking strategies (control incentives) to the conflicted situation. The pluralistic hypothesis predicts that there is a greater likelihood that a dog willing to invest only a little energy or take minimal risks to control a resource (dog A) will relinquish control over it to a competitor with whom it has established a default-hierarchy relation and who shows an established willingness to invest more energy and take greater risks to control it (dog B). As a result of such pluralistic competition, dog A will yield ascendant priority to dog B when faced with similar conflict situations in the future, provided that need tensions and control vectors are held approximately constant. The resulting pluralistic agreement serves to reduce interactive conflict around the particular resource, but without affecting the default-hierarchy relationship holding between dog A and dog B; that is, dog A remains dominant and dog B subordinate, even though dog A yields by agreement an ascendant priority of access to the resource held by dog B. The pluralistic strategy is not only conducive to the formation of affiliative ties and loyalty, but provides a way for the dominant to maximize group control over living-space resources in a way that favors those

group members that integrate subordinate relations with it.

Among closely bonded dogs, the avoidance of interactive conflict may also be influenced by a social incentive to optimize affectionate and playful interaction or to preserve cooperative relations and trust by adhering to a principle of fairness. The formation of pluralistic relations allows dogs to compete in relatively peaceful and give-and-take ways over resources that are not unilaterally controlled by the dominant dyad member. The reduction of interactive conflict over resources that are highly valued by both dogs is provided by a unilateral default-hierarchy relation defining a rigid rule of priority to such resources, thereby reducing the risk of fighting in association with scampering contests, for example. Such competition is also controlled by mutual adherence to the rule of first possession. By adhering to the rule of first possession, many potentially competitive situations involving highly valued reward items are effectively decided in advance; that is, the dog that possesses the resource assumes an ascendant priority or claim to the resource that is respected by the other dog, even though the latter has a unilateral claim to the resource. The owner may leverage social control over both dogs by defining occasions (e.g., discriminative stimuli) and rules of access (contingencies of reinforcement) to highly valued social and appetitive resources that are otherwise unavailable for the dogs to compete over. The resulting ascendant and descendant relations between the dogs is managed by the owner to make their interaction and access to owner-controlled resources more orderly, cooperative, and harmonious.

Although pluralistic relations appear to reduce interactive conflict, such flexible agreements of privilege and access priority are vulnerable to changing motivational conditions and cheating. For example, although dog A may ordinarily acknowledge the ascendant priority of dog B to food items, dog A—if sufficiently hungry or attention needy—may cheat dog B by getting to the food item first or by butting in front of dog B for owner attention and claiming rights of first possession—a maneuver that may be perceived as unfair and provocative by dog B. Such events may disrupt the ordinary stability holding between the dogs and precipitate uncertainty or instigate overt animosities and potentially dissolve dyadic hierarchy relations by reducing social attraction and trust and integrating a despotic hierarchy based on fear and avoidance (see *Avoidance Learning and Despotic Hierarchies*). According to this hypothesis, hierarchy relations dissolve when social attraction and trust are insufficient to facilitate (1) submission by the subordinate, (2) acceptance of submission by the dominant, and (3) reconciliation. Assertions of dominance in the absence of social attraction and trust destabilize dyadic relations to heighten interactive conflict, to promote social ambivalence (anger and fear) and avoidance, to instigate dispersive tensions, and, in inescapable domestic situations, to mobilize entrapment dynamics and survival modes conducive to the integration of a reactive coping style and autoprotective adjustments. The necessity of social attraction for facilitating hierarchy relations may ensure that those individuals that enter into the hierarchy bond with the dominant are affectionate and trusting toward the dominant and are received as objects of fondness by the dominant, thereby establishing an organization based on affection and trust conducive to mutual appreciation and harmony, but while serving the self-interests of all involved.

Scrambling Competition

The probability of overt fighting is related to the strength of competing vector momentums set against the relative social competence, mutual affection, and trust exhibited by the dogs. Under conditions of heightened excitability and sudden or unexpected change, the momentum of control vectors may be significantly increased and doubly so for rare or highly valued resources. Although the social codes associated with the rule of first possession are generally conducive to reducing competitive conflict over objects in possession, the rule may also increase control vectors and incentives to reach the object first. Scrambling competition may be particularly problematic

in situations where a highly motivated and quick subordinate may be able to get to objects of interest first that are ordinarily held exclusively by a slower but more aggressive and dominant dog. Under such circumstances, both dogs may escalate competitive tensions under a perceived violation of their right of access and privilege to the item. For example, if two dogs have formed unilateral dominant-subordinate relations with respect to food access, the subordinate is obligated under circumstances of conflict to defer to the dominator, except when the subordinate is in possession of the object or location first. Unlike the relative hierarchy formed in the context of pluralistic relations, unilateral relations promote a rigid dominance hierarchy with respect to certain resources. The rule of first possession conflicts with this rigid determination of access priority and privilege by giving the subordinate special rights in association with items already in its possession, thereby making strategies of first access of adaptive value to subordinates and giving them loop holes for securing control over highly valued items held exclusively by the dominant member. The successful scrambler may also take advantage of owner support, whereby aggressive threats exhibited by the dominant member in association with scrambling contests may be punished by the owner, thereby giving the subordinate an unfair advantage.

Ontogeny of Play and Fighting Among Dogs

Competition between littermates first emerges in the context of relatively symmetrical need tensions blindly propelling them toward the mother's teats. These passive (at first) control vectors enable the puppies to fully exploit the nutritive resources controlled by the mother. Access to the resource (e.g., the most readily available teat) is spatially and temporally determined in such a way that it can accommodate only one puppy body and mouth at a time. Initially, competitive success depends on scrambling success, that is, the ability to get to the teat first. Since the resource cannot be shared, it becomes, at least for the moment, the exclusive possession of the puppy that reaches it first, perhaps prefiguring the rule of first possession. Unlike piglets (Hafez et al., 1962) and kittens (Rosenblatt and Schneirla, 1962), which establish fairly rigid teat orders, puppies do not appear to show such orderly teat preferences but instead persistently "battle for a nipple" (Rheingold, 1963:176). Puppies with the strongest appetitive need tensions are likely to generate the strongest scrambling efforts, thereby enabling them to reach teats first and to stay on them once attached. As a result, these successful scramblers may derive nutritive benefits that support growth and other potential fitness advantages, including an enhanced ability to compete.

Dependency relations between the mother and puppy during the first week or so of life primarily revolve around the regulation of alimentary functions via nursing and tactile stimulation, whereas dependency relations among littermates primarily consist of thermoregulation, mutual orientation toward the mother, and the collective initiation of nursing bouts and sleeping. As a puppy develops, it shows increasing autonomy with respect to its dependency on the mother and littermates. The emergence of social dynamics reflects this developing trend toward autonomy. With increasing autonomy, a puppy learns to relate to the other as a separate entity and forms relations and attachments. The autoregulation of emotional states and impulses is a crucial aspect of the organization of social relations, an adaptive coping style, and secure attachments. In addition to learning how to regulate emotional states and impulses, active rivalry for maternal care and other resources appears to enable rivals to learn how to alloregulate one another through the exchange of various social threat and appeasement displays. However, under adverse conditions, persistent conflict and power-dominance tensions may gradually cause mutual repulsion to exceed social attraction between rivals. Under the strain of competitive tension, where the attraction for local resources exceeds the social attraction between competitors, a pattern of increasing intolerance and agonism may emerge (loner-

dispersal mode), whereby the subordinate is unable to yield submission displays and the dominant (despot) is unable to accept such displays even if they should occur. The result of such interaction is increasing intolerance and avoidance leading to social disintegration. In contrast, under conditions of comfort and safety, social attraction and playfulness will tend to exceed social repulsion gradually transforming competition into cooperation, fear into affectionate submission, avoidance into reconciliation, and despotism into the integration of harmonious pluralistic relations based on fairness and the stabilizing influence of a default hierarchy (see *Unilateral, Bilateral, and Pluralistic Relations*) and a VSS.

Exploitative Competition, Sibling Rivalry, and Emergent Fair Play

The emergence of play fighting between competitors in accordance with a principle of fairness may originate as a secondary adaptation to parent-offspring conflict. Without fair play, competitors would remain conflicted over the sharing of resources and would be constantly in search of taking advantage and getting more at the expense of others via the integration of despotic hierarchy relations. Play serves to transmute competition into cooperation. According to this hypothesis, the gratification associated with play fighting may trace back to the mother-offspring conflict and the associated social attraction/competition conflict emerging between sibling rivals struggling to maximize their share of maternal care. As such, the emergence of play fighting may contribute to the resolution of these primal sources of conflict. Play is a bridge between social attraction and competition mediated by an emergent principle of fairness. According to this hypothesis, the drive to exploit the mother is incorporated into dynamic modal relations consisting of playful exploitative exchanges between sibling rivals (see *Play, Social Engagement, and Fair Play*). The exploitative incentives and advantages taken, given, or denied during play bring the puppies together to play fight arouse precocious sexual, predatory, and fighting sequences that are kept in check by an emergent give-and-take sense of fair play and a shared desire to keep the play activity going. Adhering to fair-play rules and codes enables play partners to get the most out of their mutual exploitation.

Play, Social Engagement, and Fair Play

Competent social engagement skills and tolerance appear to be developmentally dependent on the activation of age-appropriate play activities and the integration of social codes based on fair play. During playful sparring activities, fair-play codes of conduct appear to emerge in the context of give-and-take exchanges controlling aggressive behavior. Puppies learn during bouts of play fighting that, if they exceed a certain limit in how hard they bite or bite in the wrong place, the partner will either yelp and quit playing or retaliate by attacking them. Such give-and-take dynamics appear to have long-term effects on a dog's ability to moderate aggressive behavior and impulsivity in adulthood as well as helping to facilitate the organization of social behavior based on a principle of cooperative fair play. Lund and Vestergaard (1998) traced the appearance of social investigation, play, and agonistic behavior in four litters of dogs consisting of Siberian huskies, English springer spaniels, and mixed breeds. They found that play interactions were closely associated with agonistic behavior, observing that the number of play interactions initiated was closely correlated with the number of agonistic interactions received and, conversely, the number of playful interactions received was closely correlated with the number of agonistic interactions initiated. These findings are consistent with the fair-play hypothesis, whereby playful and agonistic interactions facilitate give-and-take exchanges and the modification of social behavior in accord with a principle of fairness.

During development, the ability to play without fighting gradually results in the integration of stable friendly relations, whereas individuals that cannot play without fighting gradually disperse. The notion that infant social contact and play might help to mediate behavioral changes conducive to social inte-

gration and the moderation of adult impulsivity and aggressiveness has been studied in farm animals and laboratory rodents. For example, Price and Wallach (1990) found that if hand-reared Hereford bulls were denied access to other calves in infancy, in adulthood the bulls showed increased impulsivity and aggressiveness, making them dangerous for caretakers to handle. In contrast, hand-reared bulls that had been allowed to remain in close contact with other calves appeared to learn from an early age to inhibit aggressive impulses in order to avoid the retaliation of others. Similarly, rats deprived of social contact and play early in life exhibit a variety of deficits in their abilities to cope with social challenges (Van den Berg et al., 1999). In particular, rats deprived of early play with conspecifics show a significant impairment in their ability to submit when attacked and to prevent additional attacks by remaining immobile. After social defeat, play-deprived rats appear to go into a disorganizing state of allostatic hyperdrive, showing a higher level of corticosterone and NE than controls. The increased reactivity to social stressors exhibited by play-deprived rat appears to impede their ability to effectively initiate and maintain inhibitory control. Play-deprived rats also appear to be more susceptible to irritability and reactive aggression, showing an increased frequency and magnitude of attacks delivered to cagemates in response to aversive stimulation (Potegal and Einon, 1989).

Model/Rival Theory, Fair Play, and Sibling Hierarchy

The establishment of sibling hierarchy relations appears to be strongly influenced by bystander effects and model/rival dynamics. Observing the relative fighting abilities of littermates may change a bystander's estimation of the rivals' resource-holding potential (Dugatkin, 2001), thereby making it more or less likely for the observer to challenge or defer to the competitors in the future, based on the outcome of the fight. Watching siblings compete over valued objects may play an important role in the way complex hierarchies are formed and social codes inculcated, perhaps serving to reduce the amount of actual fighting needed to stabilize competitive tensions among group members. In addition to bystander effects, some puppies may adopt controlling or yielding roles by modeling the behavior of sibling rivals competing over attractive resources, that is, scripting hierarchy-relevant roles without ever actually competing themselves. Observing that certain interactive scenes regularly trigger overt fighting between littermates may transmit code-relevant information to a bystander that is conducive to fair play and cooperative interaction. For example, the bystander might observe that many fights develop in the context of rights of first possession, perhaps causing it to be less competitive over objects already in a rival's possession in the future. The dog's capacity to incorporate social codes and scripts via model/rival learning appears to be highly developed, and such learning may represent a social cognitive adaptation that has a close functional relationship to social play and the evolution of fairness.

The model/rival hypothesis also predicts that, after observing a fight in earnest between sibling rivals in which a winner and a loser outcome occurs, more inhibited puppies (trait-anxious introverts) will tend to identify with the loser (rival) and adopt loser-scripted roles with respect to the winner and other puppies in the group similarly perceived as possessing a high resource-holding potential. On the other hand, puppies operating under a more confident social orientation (trait-aggressive extraverts) will tend to identify with the winner and adopt winner-scripted roles with respect to the loser and other puppies perceived as subordinate in the group. As the result of model/rival learning, clever and exploitative extraverts might increase social rank and resource control by merely putting on a confident display of winner-scripted role playing, essentially mimicking the attitude and mannerisms of the dominant model. This role-playing strategy might work to obtain significant advantage and social power, at least so long as the actor avoids a competitive scene and contest with the dominant model and thereby risks revealing to bystanders its true resource-holding potential. Interestingly, the

ascendant role player may inherit a default leadership role in situations where an overly aggressive dominator fails to obtain the friendly acceptance of the group. The ability to use dominant signals to achieve rank without fighting and social codes of fair play to maintain social harmony and peace is likely correlated with a high level of intelligence and social adaptability.

FAIR PLAY, EMERGENT SOCIAL CODES, AND CYNOPRAXIS

Species-typical social codes and rules of fair play appear to emerge in the context of play, and some of these canine social codes may not develop in the absence of social or object-mediated play. Social codes and fair-play rules help to regulate potentially disruptive behavior around objects (e.g., rights of first possession) and define how, when, and where coplayers can bite one another. In addition to bite inhibition and rights of first possession, social codes based on a principle of fairness appear to impart numerous other subtle proxemic restrictions on what is allowed and not allowed in play (e.g., ambushing or biting a coplayer that is sleeping). These fair-play codes of social behavior exert a significant influence on how dogs cope with conflict in association with close social interaction and tactile stimulation while organizing and regulating proxemic relations among themselves and people. In general, obvious exploitative or unfair advantages obtained by one partner at the involuntary expense of the other result in the cessation of play or a rapid transition into overt threats or fighting. Whereas survival modes exert broad motivational regulatory control over behavior and mood by altering the significance and reward value of events, social codes appear to regulate complex exchanges and transactions between individuals via the intrinsic reward produced by code-consistent behavior. According to this hypothesis, *code-consistent behavior* facilitates social integration and cooperation, whereas *code-violating behavior* results in social disintegration, competition, and dispersal. Not only play but also many other social behaviors dependent on cooperation appear to be performed in a code-consistent manner. Since the intrinsic reward value of play appears to depend on a mutual adherence to a principle of fairness, emergent code-consistent interaction may also be acquired and maintained via the intrinsic reward associated with the give-and-take exchanges that occur during fair play. The foregoing hypothesis has many interesting implications with regard to the organization of social behavior and the evolution of cooperation. In addition to providing insight into how friendly cooperation and mutual appreciation might develop and contribute to feelings of social comfort and safety, the approach might prove useful with respect to conceptualizing some significant causes of aggressive behavior. The violation of fair-play codes (e.g., cheating or ambush) may trigger a catastrophic loss of trust and a sense of betrayal, and prompt aggressive reprisal or retribution, perhaps in search of something akin to natural justice.

Fair-play Dynamics

Canine social engagement and play depend on the presence of a safe and comfortable environment. The presence of fear or anger rapidly suppresses play and dynamic modal relations (see *Dynamic Modal Relations, Affection, Play, and Bonding* in Chapter 7). The sensitivity of play and social engagement to anxiety suggests that similar cortical pathways probably mediate both play and social engagement. During play activity, facial, motor, and vocal sequences are expressed that superficially resemble flight-or-fight behavior but independently of aggressive or fearful arousal or intent, and instead produce a joyful release of social inhibition. The social exploration and curiosity needed to confidently engage unfamiliar social and environmental stimuli appear to be strongly influenced by social attraction, fearlessness, and an ability to play. A dog's capacity to produce surprise and reward while exploring or playing is coupled with an increased behavioral flexibility to cope with the risk and uncertainty associated with such activities (see Spinka et al., 2001).

Constraints on play activity appear to promote social attentiveness, empathetic appreci-

ation, and compromise. The continuation of play fighting depends on the ability and willingness of play partners to regulate exploitative and power-dominance impulses in accord with a principle of fairness (Bekoff, 2001b) and to participate in a way that keeps the activity fun. To play fairly entails that a dog devote attention to the effects that its actions have on the play behavior of the partner and to adjust its actions in a give-and-take manner to accord with the changes observed. To play well, a dog must possess a rudimentary appreciation of the emotion and covert intent of the play partner and a belief that its actions will affect what the play partner does in return, suggesting the possibility that the dog might possess a rudimentary theory of mind (Horowitz, 2002). During play, dogs take turns in the exchange of gambits and play off one another's actions in kind, thereby setting into action play-mediated pressures conducive to a do-unto-others principle of reciprocation and fairness. Offenses to fair play and slight injuries incurred during play are more likely to incur conciliatory gestures, and such efforts are more likely to be accepted than might be the case following a serious fight. As a result, play may help to mediate tolerance and help to facilitate social skills necessary to reconcile following more serious offenses or injuries.

Although play exchanges and transactions gradually result in a shared construct of fair play, the course of play activities is only loosely determined, and some exchanges will result in mismatches relative to what the individual players might consider fair. Exchanges perceived as more than fair result in an advantage to the player taking them and a disadvantage to the player giving them, whereas exchanges perceived as less than fair result in advantages to the player making them and disadvantages to the player forced to accept them. Imbalances resulting from advantage and disadvantage during play are translated into social attraction and repulsion dynamics and proxemic relations. Learning to give advantages in order to receive advantages or to avoid disadvantages in the context of fair play is hypothesized to prefigure the development of pluralistic ascendant and descendant relations. In general, play exchanges and transactions that are perceived as more than fair are play enhancing (promoting social attraction), but only to the extent that the receiving play partner reciprocates in some way in accord with the principle of fairness. However, if the reciprocation given by the coplayer is not forthcoming or perceived as being less than fair or as selfish, the ultimate effect of the original more-than-fair action will be play diminishing (promoting social repulsion), unless the generous player is strategizing for the sake of some future advantage unknown to the selfish player taking the favors but not returning them. An overly generous player that continues to play despite repeated and unreciprocated sacrifices may gradually become an object of exploitation and aggression. As a rule, both overly generous and overly selfish players introduce discord and hazard into play activity via violations of fair-play codes.

Play and Learning to Cope with Social Uncertainty

Playful transactions involve a considerable element of uncertainty, requiring that coplayers form flexible and friendly expectancies about the other's play behavior and intent. As a result, play appears to promote learning that enables dogs to optimistically appraise and respond to social uncertainty by giving a default benefit of doubt to others. As such, play can be viewed as learning to trust while interacting with others in accord with a principle of fairness, as opposed to the selfish and self-limiting advantages obtained by means of power-dominance struggles. Just as learning to trust entails that one accept and cope with a certain degree of risk and uncertainty, the goal of play is not merely to interact fairly, but to interact in ways that enable coplayers to optimize social advantages gained at the expense of the other in the context of fair-play exchanges. Play appears to enable dogs to confidently navigate through uncertain and unfamiliar social situations under the heightened social attraction and reward afforded by trust. The reward associated with play is hypothesized to serve a cortical training function, enabling dogs to cope better with unex-

pected and uncontrollable stressors associated with domestic life (e.g., startle, strangeness, and uncontrollable events). Consequently, play in combination with the canine antistress system may improve a dog's ability to maintain an adaptive coping style while experiencing social circumstances that might otherwise promote reactive behavior.

Play not only enables dogs to cope with social uncertainty, it may also instruct them on how to use uncertainty purposefully in the context of benign deception strategies. A variety of faking-out, teasing, and deceiving tactics and exchanges are performed in the context of friendly play. Players appear to learn to take advantage of one another by means of teasing and enticing the coplayer rather than by coercing and threatening it. Players increase the momentum of play when they are getting more advantages from the play partner than they expected to receive (surprise) and hesitate or inhibit play when they get fewer advantages than expected (disappointment). Play becomes merely boring when it is just equal or entirely devoid of competitive tension and risk. Despite the momentary ups and downs, the net accumulation of advantages taken and disadvantages incurred during friendly play is generally fair, but with a variance that may slightly favor one of the players at the expense of the other. If the inequities during play are perceived as being too great (unfair), the disadvantaged player may quit or play may precipitously slip into a fighting-in-earnest mode. To avoid some of the pitfalls associated with play fighting, mature players may instruct younger coplayers on how to play fairly by engaging them in object play (e.g., running about holding a long stick in common). If one of the partners pulls too hard, the stick is dislodged from the other's mouth and the fun ends. Tug games may serve a similar instructive function. In addition to object play, a sense of fairness appears to motivate adults and large powerful dogs to handicap themselves to better sustain play with younger or smaller coplayers.

Play, Fairness, and Social Leadership

A dog's propensity to engage, disengage, or confront strange dogs appears to be strongly influenced by social attraction and repulsion, social engagement skills, individual emotional differences affecting reactive thresholds, and cognitive abilities to process subtle social signals. Most dogs show more social attraction than repulsion toward unfamiliar dogs and rapidly approach one another up to a point where repulsion dynamics may cause them to hesitate (conflict distance) and engage in more circumspect and reciprocal social investigations that eventually transition into play. Unlike the extreme behavior of fearlessly obtrusive or power-seeking dogs, most dogs require an introductory phase of mutual investigation before proceeding to more playful or agonistic interaction or disengagement (cutoff). The introductory phase between unfamiliar but friendly dogs is mutually flirtatious and exploratory, consisting of genital investigation and licking. In addition, dogs appear actively and, at times provocatively, to probe one another with sudden fits and starts of activity together with metasignals (e.g., play bow and play face), perhaps to uncover the other's intent, level of irritability, and willingness to play. The play of friendly but unfamiliar dogs is often of a sexual nature. Playful chase-and-evade games, feigned stalk-and-charge sequences, and sparring activities are also frequent and sustained. The playful care seeking and caregiving, competition, sexual exploration, and predatory components may enable dogs to rapidly explore one another and to get on familiar and friendly terms, while stimulating a variety of reward systems conducive to social engagement. Playful sexual behavior may mediate effects akin to pair bonding, whereas caregiving and care-receiving sequences may stimulate maternal/offspring-like bonding processes via the release of oxytocin and prolactin. Predatory-like sequences and reversals may stimulate reward via the activation of the seeking or behavioral approach system (BAS), while play fighting might promote feelings of affiliation and trust. The proxemic scenes and behavioral topographies exhibited by dogs engaged in play may reflect transient states of emotional arousal relevant to the functional system activated by the play activity (e.g., sexual, predatory, and agonistic or power dominance).

When performed in conformity with a principle of fairness and mutual appreciation, these emotional states may synergistically interact to produce a state of joy. However, when activated in the absence of social attraction and fairness, these systems may produce an opposite set of synergistic effects promoting behavior akin to cruelty. Consequently, play in the absence of social attraction and a principle of fairness may quickly transition into exploitation or fighting, resulting in social repulsion and dispersive tensions.

Affectionate proximity seeking and gestures of a friendly nature are common between playful dogs when they are not engaged in play (e.g., gentle facial investigation, sniffing, and licking of the ears). As dogs become familiar and start to integrate friendly relations, they may mutually assert limits on one another, often by the most patient and gentle means, including, if necessary, by direct stare, fang flashing, baring teeth, inhibited nips, and nonbiting snaps or lunge barks. Gradually, a friendly leader-follower bond emerges with the most socially competent, physically active, and confident dogs usually taking a leadership role. Such leaders often show an extraordinary *play drive* and appetite for friendly social interaction. Leaders establish harmony by means of example and adherence to social codes, which includes a fastidious caution with respect to the first law of canine etiquette: the right of first possession. Leaders of this type appear to inspire a subtle form of imitation, submission, and the integration of a voluntary subordination strategy. In contrast, a socially exploitative dog responds to the approach of an familiar dog with a rapid transition to obtrusive play, whereas a socially despotic trait aggressor may stridently approach an unfamiliar dog and compel it to fight. Both of these types violate the principle of fairness necessary for friendly cooperation and play.

Intraspecific State and Trait Aggression

Dogs exhibiting a power-dominance orientation toward unfamiliar males may deliver vigorous and unprovoked attacks based solely on gender and unfamiliarity. As youngsters of 4 to 9 months of age, or occasionally younger, such dogs may suddenly become aggressive and intolerant of close proximity with other dogs—an intolerance that may persist throughout their lives despite intensive positive socialization efforts. The propensity to fight shown by such dogs does not appear to be aimed at integrating hierarchical relations, since trait aggressors will seek a fight with the same dog that the day before was thoroughly intimidated. Many of these dogs appear to operate under the influence of a persistent motivation or drive to fight. A useful term for this sort of agonism is *intraspecific trait aggression*, emphasizing a strong genetic influence predisposing certain dogs to fight. Trait aggression reflects a persistent disposition or temperament trait to experience other dogs as objects to attack. In contrast, dogs exhibiting state aggression fight only to escape or avoid an unconditioned social stimulus evoking frustration or irritation. Whereas state anger is highly emotional and intrinsically aversive, trait anger appears to mediate fighting under the influence of quiet attack and power-dominance motivations (reward incentive). The notion of trait aggression suggests an enduring predisposition to seek out and confront other dogs for the purpose of picking fights, whereas state aggressors fight back or retaliate, exhibiting an unwillingness to submit in response to provocative stimulation (low-fight/high-fear thresholds). Trait aggressors appear to derive reward from fighting, whereas state aggressors obtain reward by avoiding fights (threat display) or fight to escape the fight-evoking situation. The notion that aggression might be rewarding has been recently demonstrated among mice trained to perform an instrumental nose-poke task for the opportunity to attack an intruder for 12 seconds (Fish et al., 2002). These findings suggest that the reward associated with trait aggression may be largely derived from the positive emotions (elation) associated with trait anger and the activation of the BAS (Harmon-Jones, 2003).

Consistent with the intrinsic-reward hypothesis, trait aggressors may develop various strategies to improve the likelihood of

getting an opportunity to fight, and show a preference for locations of past fights. On walks, such dogs may lag behind or, if permitted off leash, they may take advantage of turns or intersections with an apparent hope of putting themselves in a better position to encounter another dog. The trait aggressor may urine mark to attract the marking activity of potential rivals and thereby track their general activity and whereabouts. Urine marks are carefully examined and licked, and surface earth is sometimes slightly upturned while inspecting them. Repeated exposure to the urine odor of a potential target may exert a potent instigating effect on trait aggression. When entering into areas associated with past fighting, trait aggressors often urinate or defecate and then cut deep signature marks into the ground by forceful scratching. Some of these dogs become very stealthy and deceptive, appearing to minimize signs of arousal and intent in order to put the owner at ease before breaking free to attack or lunging and grabbing the other dog and refusing to let go. Trait aggressors live to fight and habitually provoke aggressive interaction with other dogs, irrespective of apparent territorial incentives, appearing to seek aggressive encounters as something akin to a sport activity. Trait aggressors often approach other dogs excitedly with unwavering eye contact and present an inflexible and propped-up appearance that may be misinterpreted as an excited prelude to play. The carriage of the tail expresses social confidence and determination, and trait aggressors usually hold their tails in a stiffly erect position that may quiver and twitch with anticipation. If ignored or not reciprocated with complete submission and obsequiousness, these displays are followed by rapidly escalating threats, including intrusive proximity and contact posturing, an agonistic T orientation, mouthing or nervously licking at the scruff, rising up and mounting actions, and a point of no return. Some trait aggressors show a wide-eyed look of glee (clown face) and an excited tight tail wag just before launching into an attack. Experienced trait aggressors may decide to attack while at considerable distance from the target. In such cases, the aggressor may skip *foreplay* niceties and execute a frontal charge and crash directly into the target, thereby securing an immediate and perhaps devastating advantage. Trait aggressors fight vigorously but appear to maintain emotional composure and often do not bark before attacking.

Many of these dogs seem to be governed by something akin to a chivalrous code that seems to obligate them to fight with other adult male dogs of approximately the same size or larger, whereas they show extremely friendly behavior, bordering on fawning, toward females, with whom they often enact playful courtships. Such dogs appear to fight as though their honor and self-respect depended on it. Trait aggressors are usually gentle and paternal in attitude toward puppies, but are not above serving out harsh punishment to obtrusive juveniles. Although neutered dogs are not immune to attack, in some cases experienced trait aggressors appear to treat them differently, almost as though they did not exist. Some trait aggressors may perceive neutered dogs as being neither male nor female and consequently treat them as nonentities—a feature that suggests a possible gender-specific olfactory trigger or modulatory mechanism controlling such behavior. As they age, trait aggressors typically become less aggressive toward other dogs and seem to retire from fighting altogether in old age. Unlike male aggressors, female aggressors are often equally aggressive toward males and females (see *Virago Syndrome* in Volume 2, Chapter 7). Female aggressors appear to be motivated to fight by different incentives than males (trait/state motivations), showing greater contact intolerance toward other dogs, and, unlike male counterparts, female trait aggressors do not appear to derive the same amount of intrinsic reward from the fighting activity and probably fight for different reasons. Whereas male trait aggressors might be described as fighting for the thrill, female trait aggressors appear to fight for the kill, but are usually satisfied with merely getting rid of the other female. The severity of fighting between females appears to exceed that of comparable males, especially in fighting between dogs sharing the same household. Severe and persistent fighting between females living in the

same home is often motivated by social repulsion and dispersal incentives.

Controlling Intraspecific Aggression Toward Nonfamilial Targets

Unfortunately, owners of dogs that like to fight are often under the influence of denial, refusing to appreciate fully the danger posed by their dog's appetite for fighting. Such owners are prone to offer capricious interpretations and rationalizations to lessen the seriousness of the behavior or to find excuses for it. Many owners appear to treat dog fighting as a normal canine nuisance behavior and are reluctant to seek professional help to control it (Baranyiova et al., 2003). Occasionally, owners may get a vicarious thrill from the dog's eagerness to fight. Such owners may allow a serious problem to develop or intentionally facilitate a dog's propensity to fight. Many owners of aggressive dogs are strikingly irresponsible and permissive with regard to the lackadaisical effort they put into keeping their aggressive dogs under control while in public. Some continue to give their aggressors the liberty to attack other dogs on multiple occasions while in public places. Roll and Unshelm (1997) found that 31% of dogs that fight do so with other dogs known to be targets by the owner in advance of the fight.

All intraspecific aggressors should undergo intensive basic training to tame their aggressive impulses. The goal of remedial training is to promote inhibitory control and introduce countermand signals that reliably interrupt attack-sequence processing and integrate more appropriate ways to cope with the presence of another dog nearby. Large powerful breeds should be exercised on muzzling-type halters attached in combination with a slip collar or a prong and closed-loop leash arrangement, as previously described. As with other cases involving aggression, graduated and massed-trial exposure, response blocking, and inhibitory conditioning can help to reduce reactive behavior and make the dog more immediately responsive to owner command. The following set of procedures assumes that the dog has received intensive preliminary orienting/TAT, thorough basic obedience training, and preliminary inhibitory conditioning.

Aggressive Tensions Around Fence Lines

A common focal point of aggression is fence fighting, which can be a serious problem and cause neighboring dogs to become increasingly agitated and aggressive toward one another. The impulse to fight appears to be intensified by daily instigative exposure to the odor and sight of agonistic targets. Laboratory animals exposed to the sight and smell of opponents but not permitted to fight show a significant increase in aggressive threats and attacks when they are finally free to fight (de Almeida and Miczek, 2002). Whenever possible, fighting dogs that share adjoining yards should be prevented from seeing one another through a fence. Stockade fencing backed with chain-link fencing buried in the ground can be helpful. With aggressive dogs that need to be kenneled in adjoining runs, it is a good idea to divide runs with a 3-foot walkway between enclosures or to separate runs with opaque dividers. Kenneled dogs sometimes break off canines while fence fighting, a significant problem with working dogs whose teeth are needed in working order. Setting up a schedule with neighbors for putting the dogs out separately can be a helpful way to avoid unsupervised encounters between the dogs. Since some dogs appear to develop increased tolerance as the result of graduated exposure, arranging to go for walks with the neighbor and dog can help to reduce tensions. During walks, the dogs should be appropriately restrained and kept far enough apart to minimize aggressive tensions. Both dogs should be discouraged from pulling into the leash and prompted to orient and sit at the least sign of building tensions. Strong emphasis is placed on positive reinforcement, with both dogs receiving vocal encouragement, petting/massage, and food rewards so long as they mind their own business. After returning home, the dogs can be walked along the shared fence line at a nonprovocative distance. Every few steps, both dogs should be prompted to sit or lie down and stay followed by appropriate rewards. If everything goes

well, the owners can initiate object-oriented play activities with the dogs on long lines. When in the yard, performing attention and recall training and playing tug and fetch can help to focus a dog's attention on activities more gratifying than fence fighting. To break up the habit of exiting the house to immediately search for the other dog or scramble to the fence, the dog should receive appropriate inhibitory training around such occasions. Taking the dog outdoors periodically during the day and engaging it in ball play and other basic-training activities can also be helpful.

Dogs showing excessive and persistent aggressive behavior toward other dogs along fence lines should receive intensive recall and halt-stay training, enabling the owner to interrupt the behavior reliably (see *Aggressive Barking, Lunging, and Chasing*). Once a high level of command and countermand control is established, the use of various behavior- and remote-activated devices can be considered, as needed, to enhance inhibitory control over barking excesses and charging at the fence line. The toss of a scented shaker can or jangle of throw rings can be highly effective for interrupting and deterring some fence-related problem behavior, especially in situations where alternative behavior is prompted and rewarded consequent to the startle event. Some electronic devices currently available incorporate both remote and bark-activated capabilities that can be extremely effective when properly introduced. Although electronic training tools are of significant value in such situations, they can also produce significant harm if used improperly. As things progress, various behavior-activated and remote techniques can be applied as appropriate and needed to bring the behavior under more reliable control. For example, in persistent cases, a spray deterrent or electronic containment device might be used to keep the dog away from the fence line.

Attention Control and Gradual Exposure Techniques

Since preattentive processing anticipates the mobilization of arousal leading to aggression, preemptive control is established in advance of a dog showing overt signs of aggressive intent or behavior in order to promote an autonomic state and emotional establishing operations conducive to behavior incompatible with aggression. A conditioned orienting stimulus or a diverter/disrupter may be used to evoke the necessary motivational changes. Diversion with the orienting stimulus or food can be highly effective, if followed by efforts to shape incompatible behavior. If the dog is diverted with food, it is required to perform at least five simple responses (e.g., repeated orienting and eye contact, approach and sit, stand-stay, and so forth) before being allowed to turn back toward the target. Alternatively, a DRO schedule can be implemented whereby the dog is given a reward after some brief period has passed (3 to 5 seconds), provided that it does not show aggression toward the other dog. The delivery of periodic surprise consisting of a highly valued food item (e.g., chunks of chicken, beef, or fish) appears to help integrate new expectancies and to mobilize active modal strategies incompatible with aggression. Access to a rubber toy containing the reward can be very useful in support of DRI and DRO training and for producing a sustained interruption of aggressive arousal and activating appetitive-establishing operations that may antagonize provocative arousal and set the stage to advance the exposure process. The rubber toy is attached to a 6-foot piece of rope with a handle so that toy can be pulled around and the dog enticed to follow and grab it. The dog is permitted to keep the item for a variable length of time to (e.g., 10 seconds to 2 minutes) before it is required to release it to the handler. If the dog barks aggressively or lunges during a DRO cycle, the object is taken from the dog, followed by a right-turn maneuver and directive leash prompt sufficient to secure the dog's attention and to ease the escalating tension, whereupon the dog is hauled off to a post or tree previously set up as a tie-out station. The tie-out should give the dog enough room to stand and sit comfortably but prevent it from lying down during the 30- to 60-second time-out.

In some cases, forced backing can be used in combination with the forward pattern to counteract aggressive arousal. The dog is

trained to walk backward in response to leash prompting and the vocal signal "Back" in a training setting without a target dog. For example, a backing-and-waiting routine can be incorporated into a ritual used when preparing to exit the house for a walk. At such times, if the dog charges impulsively through the door, the leash can be pulled short and pinched in the door jamb, leaving the dog in TO for 30 seconds before trying again. In situations where the dog shows aggressive arousal, it is prompted to back away five steps or so from the target before its attention is diverted with the orienting stimulus and a cycle of DRI or DRO training is initiated. A thoroughly conditioned sit-stay response and orienting/attending response can be extremely useful in such cases. After the dog is prompted to sit, it is periodically prompted with a smooch to make eye contact, followed by the vocal bridge "Good" and a variable or sustained reward. Sustained rewards are provided to the dog by means of sustained petting or massage and several small pieces of food. As the dog shows signs of relaxing, it is walked 5 feet closer to the target and rewarded. If the dog becomes aroused again, though, it is backed off once more from the target, but perhaps more forcefully than before. Whereas forward locomotion is associated with the activation of the seeking system and reward, backward locomotion is mildly aversive and associated with inhibition and retreat. The combination of orienting/TAT, DRI-DRO training, forward-exposure, and backward-exposure procedures with appetitive surprise, and sustained reward, appears to provide complementary modulatory influences over arousal shifts.

Another gradual approach strategy incorporates the starting exercise and basic obedience modules that are first trained to a high level of proficiency, with the dog going to the trainer's left side, sitting, standing, lying down, and staying put until released by the handler (see *Stay Training* in Chapter 1). The dog is started at a nonprovocative distance and turned about to face the target and prompted to sit, rewarded, and released. The starting exercise is repeated over and over again until the dog turns away from the other target, goes to the handler's left side, and sits squarely without hesitation. The dog is then prompted to stand by the handler taking one step forward on the left foot, and again the dog's attention is prompted by means of its name or orienting stimulus (e.g., smooch, squeak, or whistle). Orienting prompts are repeated as the dog is walked at a slow pace toward the target, with the orienting stimulus and click sequence occurring every three to five steps followed by the SE and high-value surprises delivered periodically by hand or tossed to the dog. At the first point in the forward progression in which the dog refuses to yield its attention to the trainer, the handler takes two or three steps back while signaling the dog to the starting position. If dog fails to sit squarely, the handler again steps back and guides the dog into the position. After a moment, the dog is prompted to stand and then to sit, followed by another stand and then prompted to sit and lie down once more. This pattern, consisting of the sit, stand, sit, down, and stand cycle is repeated, with each module of the routine taking 5 seconds to complete, with sustained reward (vocal reassurance, petting, and food), until the distance walked backward is regained in an inchworm fashion. When the original point is reached, the dog is release with an "Okay" and engaged in tug-and-fetch play on leash. If the dog turns from the toy toward the other dog, it is prompted to the starting position by taking two or three steps back and guiding it around. The starting routine is repeated with variations (e.g., left and right approach, interrupting the automatic sit, heeling the dog out of the starting position, and leaving the dog in a sit-stay). Interrupting the dog's attention at the earliest sign of shifting arousal is preferred, but, if arousal escalates at any time into an overt threat (e.g., barking or lunge), a directive prompt or saccade (all-stop procedure) and right-about turn is carried out, whereupon the dog is repositioned at a less provocative distance from the target where the starting exercise with orienting stimulus, bridge, and social and appetitive reward are repeated.

Prompting the dog to orient and repeatedly guiding it into the starting position until

it goes to the position and sits without hesitation can be helpful for integrating inhibitory stop-change control. As the dog begins to sit, the vocal bridging stimulus is delivered, followed by relaxing petting, the presentation of a food reward of significant value, and massage as the dog continues to remain compliant. Inhibitory conditioning is focused on the sit-stay routine rather than punishing overt lunging and threat behavior. In some cases, scented compressed air can be delivered silently, followed by a countermand (e.g., "Stop!" or "Out!") and a brief burst from the modified air pump can effectively grab the dog's attention and generate rapid inhibition without risk of damaging the dog's ears or the ears of bystanders, as might occur with a nautical horn used at close quarters. Exposure to other dogs is carried out under varying conditions and degrees of interactive exposure and risk, as determined to be appropriate, safe, and most likely to succeed. Exposure is best mediated in the context of practicing a variety of basic obedience exercises on a 6-foot leash and later graduating to long-line control. Muzzling should be considered for the sake of public safety in the case of a dog that represents a significant threat to other dogs and people, at least until the handler has acquired the necessary skills and experience to interrupt and reliably control the dog's aggressive behavior whenever and wherever it occurs.

Since many aggressors appear to derive significant gratification from the opportunity to fight, appetitive counterconditioning and reward-based shaping procedures are of limited value, especially for dogs that would place the opportunity to fight above the acquisition of social attention, food, and play. Persistent aggression toward other dogs not belonging to the household can also be brought under stimulus control by training the dog to turn on and turn off aggressive arousal and threat displays. This particular procedure is especially useful with trait aggressors. However, before implementing such a procedure, serious consideration needs to be given to the owner's dog sense and dedication, because the approach, if improperly implemented without appropriate inhibitory control, may only make the problem worse. Controlling trait aggression depends on rapid decisions and actions in response to the earliest signs of aggression. For effective control, directive and saccadic prompts need to be delivered with sufficient conviction and strength to bring the developing attack sequence to a dead halt. The application of preemptive prompts in anticipation of aggressive arousal can be highly effective for establishing inhibitory control. These general control requirements can be expedited by electronic training (see *Electronic Training and Problem Solving* in Chapter 9). The electronic collar is introduced in the context of reward-based training and only after basic modules and routines have been well conditioned. Enhanced attention control, recall, halt-stay, and sit-stay and down-stay training are emphasized. The dog is gradually exposed to other dogs in incremental steps, and sequences similar to the procedures and variations are used to stage exposure, as previously described (see *Aggressive Barking, Lunging, and Chasing*). The exposure procedure can be highly effective when performed in association with electronic training for mediating avoidance control over aggressive impulses. In addition to mediating avoidance learning and improving inhibitory control, the electrical stimulus may help to offset intrinsic reward derived from the dog fighting activity.

FIGHTING BETWEEN DOGS SHARING THE SAME HOUSEHOLD

Preliminary Considerations

Assessing and controlling fighting between resident dogs is multifaceted (see *Aggression Between Dogs Sharing the Same Household* in Volume 2, Chapter 7). The first step in the process is to assess the frequency and severity of past incidents. In addition to obtaining detailed information about the specifics (e.g., eliciting triggers and situations), a summary of injuries to the dogs should be obtained as well as injuries to people that resulted from redirected aggression or accidental bites that occurred while fighting dogs were being separated. Since interdog aggression may occasionally stem from increased irritability and

mood changes resulting from an undiagnosed medical condition, it is important to collect information about the dog's health and recommend that a veterinary examination be performed to exclude such potential factors. In cases involving damaging fights that have resulted in significant injury, various strategies for keeping the dogs apart should be discussed and implemented, including the possibility of rehoming one of the dogs. Sturdy gates, tie-out stations, and crates can be useful in the management and training of such dogs. The trainer should thoroughly explore the risks involved to the dogs, as well as risks of injury to family members that can stem from redirected attacks, or accidental bites that might occur if someone attempts to separate the dogs while fighting. Finally, in some cases, what appears to be fighting to a novice owner is actually just play (Figure 8.4).

Ability and Readiness to Fight

Dogs appear to rapidly appraise each other's relative ability and readiness to fight, referred to as *resource-holding potential.* Resource-holding potential is often correlated with size but is also strongly influenced by need tensions and control incentives, that is, the individual's determination to establish control over a contested resource or place. A small but highly motivated dog can defend a valued object against a much larger but less motivated challenger. The effects of past victories and defeats appear to influence significantly the dog's readiness to fight, perhaps by switching on or off neuroendocrine modes conducive to confrontation or retreat behavior. Perhaps the most important considerations affecting resource-holding potential are prior residency and age. Age and prior residence appear to confer special advantages and expectations with respect to privilege and governance rights. Newly introduced young dogs appear to defer as obligatory subordi-

FIG. 8.4. From appearances, these dogs look as though they are fighting with some degree of seriousness, but actually they are playing and have never fought in earnest to inflict or defend against injury.

nates to the most original resident of the home or living space, which is often the oldest dog in the group. The implication of age in the organization of hierarchy may stem from increased experience and prior use of the home range. Established residency appears to imply ownership and control over the entire living space, at least as regards canine interests.

To form secure social and place attachments, the newcomer must enter into pluralistic relations with the resident, but, to achieve this level of social integration, the resident and the newcomer must share mutual social attraction that is sufficient to integrate dyadic hierarchy relations. As such, social attraction and repulsion are the most primary modes of social grouping or dispersion. The ease with which males and females integrate social relations and tolerate the introduction of a nonrelated puppy is probably based on attractive preferences shown toward the opposite sex and a readiness to integrate young animals into the familiar social structure. In addition to residency, social status is broadcast by a dog's attitude, with the most conspicuous and consistently reliable indicator of relative dominance represented in the way in which the dog carries itself—not its size or physical strength. A feisty 10-pound dynamo with *attitude* can challenge and roundly subordinate other dogs many times its size as though it were perfectly natural and correct, especially if it is older and holds privileges of prior residency. However, the ultimate determinants of dominant or subordinate status are closely related to temperament differences, especially relative fearlessness, excitability, and aggression thresholds. Holding other variables constant, dogs that are relatively shy and inhibited are typically more likely to avoid confrontation and to back down if confronted, whereas dogs that are relatively bold, excitable, possessive, and prone to aggressive impulsivity are more likely to confront other dogs and fight if confronted.

Stake-and-Circle Test

If uncertain about an adult dog's propensity for fighting, a potentially useful way to evaluate relative dominance and social tolerance is a modified stake-and-circle test, which is based on a procedure devised by Le Boeuf (1967) to evaluate interindividual relations between dogs. The test situation used by Le Boeuf consisted of a stake and 5-foot chain and harness attached to one dog and a large arena that allowed the other dog to rove about freely. Approach behavior was quantified by counting the number of times that the roving dogs made contact with tethered ones and the amount of time they spent in close proximity (i.e., remained within the circle defined by the chain). Dogs did not appear to become more aggressive when tethered; in fact, roving male dogs initiated most of the aggressive encounters, with the tethered dogs fighting back or submitting. Agonistic encounters between the most aggressive dogs usually ended before escalating into overt fighting, with neither of the dogs submitting or reducing their animosity or willingness to fight in the future. Interestingly, the dogs that spent the most time visiting tethered dogs were also least likely to receive visits from other dogs when they were tethered. The dogs making the most frequent approaches to tethered dogs were typically more outgoing, fearless, and aggressive. These more socially outgoing and aggressive dogs appeared to establish friendly alliances and cohort relationships with certain submissive dogs toward which they showed little or no aggression. The most aggressive males initiated more visits to other dogs irrespective of past encounters. In contrast, males rarely approached other dogs that had previously defeated them. Whenever the most aggressive and fearless dogs came together, they consistently showed mutual hostility. More aggressive dogs appear to approach other dogs more frequently because the former are less fearful. The relative fearlessness or boldness of such dogs may account for their inability to establish dominance over one another. These results suggest that the stake-and-circle test might reveal individual differences associated with extraversion and social dominance.

A variation of the stake-and-circle test is performed by alternately tethering one dog (T) on a 5-foot line or cable and allowing the

other dog (R) to rove about on a 30-foot long line that is tied off at a point that allows R to reach within 2 feet of T. Roving dogs with a bold disposition will tend to approach tethered dogs rapidly, irrespective of their relative boldness or shyness, whereas dogs with a more shy disposition will tend to avoid approaching other dogs perceived as a threat. Dogs showing aggression in association with autoprotective incentives may show preemptive threats toward the approach of a roving dog but avoid the same dog when it is tethered. The basic test is performed with the owner at the midway point between the roving dog and tethered dog. In addition, two subtests are used to evaluate the influence of the owner's presence on aggression tensions. Subtest 1 is performed with the owner positioned to the right or left of the tethered dog at a point that is just out of reach of both the roving and tethered dogs. Subtest 2 is performed with the owner positioned within the reach of the tethered dog and making an excited and affectionate fuss over it as the roving dog is released. Subtest 3 is the same as subtest 2 except that, as soon as the roving dog is released, the owner immediately withdraws from the tethered dog and approaches the roving dog and makes an excited show of affectionate attention just out of the tethered dog's reach. After 30 seconds, the owner abruptly stops and returns to the tethered dog. Relatively fearful and submissive dogs may be emboldened by the presence of the owner to approach closer than they normally would, perhaps triggering animosities, whereas more aggressive and socially intolerant dogs may show heightened animosity when approached in close association with the owner.

Sources of Conflict Between a Newcomer Puppy and a Resident Dog

When bringing a new puppy into the home, many dog owners are apprehensive about how the resident dog will react to the newcomer. Although the pattern of coping is variable, most dogs gradually learn to accept and enjoy the new addition to the household. Adult dogs rarely attack a puppy to injure it, but may set limits with a severity and force that may seem excessive and inappropriate to the dog owner. Canine behavior toward puppies appears to be governed by a social code that forbids injurious bites or life-threatening attacks. Dogs that violate this social code are truly abnormal and should not be in the same household with a young puppy.

Although serious attacks are rare, irritability and intolerance toward a puppy are common. The way a dog copes with a puppy is determined by numerous developmental, experiential, and health variables. For example, due to age-related differences affecting playfulness or physical condition, older dogs are often less engaging and tolerant than are younger dogs. Highly active and intrusive puppies can be a source of significant distress for elderly dogs. Typically, a socially competent dog will rapidly establish appropriate limits and integrate social relations with the puppy that develop into a secure attachment and mutual attunement. Inhibited or insecure dogs may allow the puppy to violate normal canine boundaries with impunity and, instead of punishing it, may do everything possible to avoid it. As a result of persistent exposure to an inescapable puppy, insecure dogs may resort to compulsive barking or other rituals whenever forced into intimate contact with the newcomer. In such cases, nothing that the puppy can do will change the situation or make the insecure dog more accepting. Initially, owners may misinterpret the obtrusive play behavior of the puppy and the apparent acceptance shown by the insecure dog as an indicator of forbearance and gentleness, but the withholding of social punishment (limit-setting actions) in such cases is more often a sign that the dog has refused to accept the puppy, perhaps refusing to acknowledge its existence by passively disengaging. Further, puppy play unconstrained by fair-play limits may rapidly degrade into exploitative cruelty, whereas indiscriminate punishment of friendly social engagement and play by an overly reactive dog promotes social repulsion, dispersive tensions, and a nervous attachment. In contrast, nervous dogs may punish a puppy whenever it comes too close. Punish-

ment, as delivered by nervous dogs, is not aimed at educing submission or integrating hierarchical relations—its only purpose is to keep the puppy at a distance. Allowing a bold puppy to take advantage of an overly tolerant and insecure dog, or allowing the puppy to fall victim repeatedly to the threats and snaps of an intolerant and nervous one, may permanently prime social exchanges with reactive dynamics and expectancies. All of these problematic responses to the introduction of a puppy are related to a common denominator: insufficient autonomic balance and social attraction to initiate and sustain friendly interaction.

How a dog responds is strongly determined by the nature of already established social and place attachments. Whereas dogs under the autonomic attunement of secure place and social attachments tend to show an adaptive coping style that promotes attentive and calibrated emotional engagement (inquisitive boldness), dogs expressing nervous or insecure attachments exhibit various deficits and deficiencies that impair their ability to cope with the social demands posed by a puppy. Whereas the nervous dog lacks sufficient stability to establish social relations, the insecure dog lacks sufficient flexibility to integrate new social relations. The reactive instability and rigidity of nervous and insecure types represent significant challenges when a new puppy is introduced.

The critical issue at stake when introducing a puppy is to provide social and environmental incentives that promote mutual attraction and attachment. Outdoor activities, involving walks, play, and reward-based training activities, may serve to link the puppy with a positive QOL-index shift, thereby helping to activate survival modes conducive to social integration. The perception of an improved QOL index can be amplified by increasing the number and variety of appetitive and social rewards given to the dog during the day, both in the puppy's presence and at other times. Improving the quality the dog's diet by making small changes (adding favorite food items), or just allowing the dog to eat a small portion of puppy food at every feeding, can make a difference in how the dog perceives the new situation. In contrast, however, isolating the dog or reducing its access to valued rewards may have an adverse effect on its ability to integrate affectionate relations.

In general, the relationship between the puppy and the dog is one of imbalance on practically every level. Significantly, a puppy is far more interested in attaining the regulation provided by attachment than a dog is in giving it. From the dog's perspective, the puppy is a disruptive influence over well-established relations and attachments between the dog and the household. The owner should be encouraged not to become overly involved or attempt to micromanage the transition. Ultimately, the goal is to facilitate and foster interaction rather than attempt to dictate a relationship that depends on the owner's constant supervision to work. Generally, giving the resident dog support and the benefit of doubt in its efforts to curb the youngster's excessive behavior is beneficial. Owners who side with the puppy risk establishing a highly undesirable alliance and misperception that can exert long-term destabilizing effects. Instead of forming bonds with each other, such dogs may establish triangulated relations via the meddling owner. As a result, the puppy may become increasingly obtrusive toward the dog when in the owner's presence, with the latter becoming increasingly insecure, irritated, and intolerant of contact with the puppy.

Since social attraction is a necessary precondition for a dog to accept a puppy, owner interference may effectively block the integration of hierarchical relations. The primacy of social attraction, reconciliation rituals, and social engagement for organizing harmonious relations cannot be overemphasized. A dog that continues to avoid the puppy and treats it as a source of loss, irritation, and intolerance may become increasingly repulsed by its approach, showing a rigid and reactive pattern of avoidance and threats. As the puppy matures, it may become increasing bold and reckless in its interactions with the reactive dog. As a result of owner efforts to splice together a relationship in the absence of social attraction, the dogs may become increasingly defensive and autoprotective whenever in the

presence of the owner, until they cannot be in the same room together without restraint. Attempting to integrate dyadic relations between dogs lacking social attraction is difficult, but integrating such relations between dogs that are mutually repulsed and intolerant is often impractical and raises many QOL and welfare questions.

Introducing a New Adult Dog into the Household

Whenever introducing adult dogs, efforts should be taken to set things up for success and not to take unnecessary risks and shortcuts that might result in a fight. A fight during the introduction leaves a very durable and, perhaps, insurmountable first impression. Consequently, great care should be taken to ensure that the first encounter is as positive and uneventful as possible. Organizing the first meeting to take place in a transitional location where the resident dog is accustomed to meet strange dogs and has been exposed to a history of playful interaction with them is a useful starting point. Alternatively, arranging to take the dogs on a long walk together can be a relatively nonprovocative way to break the ice. If tensions erupt, various reward-based attention-control techniques can be helpful. Taking turns with each dog to play ball while the other looks on seems to reduce tensions while priming the dogs with arousal more conducive to positive social interaction. If animosities emerge despite precautions, an appropriate assertion of control at the instant they begin to percolate can prevent escalation and reduce the risk of reaching a flash point of no return. If necessary, a directive leash prompt is used to restore control and order before continuing the walk as though nothing had occurred. Evenhanded and decisive interruption of argumentative exchanges can help to deflate competitive tensions and make it easier for the dogs to engage in less provocative exchanges and to promote conversations conducive to mutual tolerance and eventually acceptance. The goal of the introduction is to mediate increasing familiarity to set the stage to allow sufficient social attraction to develop between the dogs to generate play. Without adequate preliminary safe interaction to mediate familiarity, an atmosphere of mutual uncertainty may block the emergence of social attraction and increase the risk of a fight breaking out instead of play. Fighting between unfamiliar dogs is not conducive to the integration of dominant-subordinate relations based on submission, but instead results in social polarization, mutual intolerance, or persistent aggressive tensions. Between strangers, the exchange of threats will either increase mutual anger and trigger fighting or increase fear in one of the competitors, thereby setting the stage for flight and persistent avoidance.

Unfortunately, due to hesitation or lack of appropriate control over the dogs, inexperienced dog owners may hesitate at the critical moment and allow the tensions to escalate and erupt into a serious fight. The owner may subsequently become increasing uneasy and nervous with the dogs interacting nearby, especially at times and places associated with increased excitement (e.g., homecomings, preparations for walks, and feeding times) and previous fighting. These various times and places may acquire conditioned associations that trigger preparatory arousal and lead to an increased risk of fighting whenever the dogs encounter each other under those evocative circumstances. These exciting situations appear to simultaneously disinhibit the dogs in anticipation of a rewarding activity with them together, but, as they interact in the close vicinity of the owner, the exciting arousal drawing them together may dissipate as overshadowed fear and anger gradually take front stage. Under these circumstances, owner anxiety may add an additional element of uncertainty to further destabilize the rapidly escalating conflict. Dogs probably do not process owner anxiety egocentrically, but are more likely to associate the changes in the owner's behavior allocentrically, that is, attribute its cause to the other dog. As a result, a possibility exists that both dogs may cross-attribute the owner's anxiety to each other. Determining specifically how different human mood states influence dog behavior is an important area of basic research that remains to be worked out in detail, but anxiety-related changes to the owner's olfactory signature

may play a role. Whereas negative owner mood states under such situations are probably processed allocentrically, positive changes in owner mood states are probably processed egocentrically. Thus, maintaining a positive and confident mood may result in helping both dogs to relax and become less ambivalent or reactive toward each other while in the owner's presence. Conversely, a worried owner may cause the dogs to interpret the situation as unsafe as the result of causes due to the other dog, thereby increasing mutual vigilance, agitation, intolerance, and the readiness for the dogs to fight. Although the precise details of the signaling system mediating these changes remain to be studied, the composite of conditioned stimuli, contextual cues, and owner anticipatory-anxiety signals may establish a hierarchy of trigger events that lead to increasing reactive arousal and set the occasion for fighting. Unquestionably, owner inexperience and lack of dog sense and training skill in such matters is a significant factor in the development of interdog aggression (see Rugbjerg et al., 2003).

Aggression between such dogs is not likely the result of dominance, as it is a conditioned behavior mediated by history of fighting and owner mismanagement. Under the influence of repeated and ineffectual interference, the resident dog may gradually turn on the newcomer at the least provocation. What began as relatively infrequent and innocuous scraps may develop into a frequent and serious pattern of injurious fighting (Figure 8.5). It is interesting to note that such dogs may not fight when left alone, but this cannot be relied on in every case, especially where a high degree of interactive tension and rejection is present and where damaging fights have occurred in the past. Further, once fighting has escalated to include damaging bouts, then the option to allow the dogs to fight is neither effective nor humane. To reiterate, once tensions have graduated beyond the level of ritual contests, staging tournaments between the dogs in order that one of them might finally win decisively and become dominant over the other is not a viable treatment option and could result in one of the dogs being severely injured or killed. Dogs operating under strong repulsion incentives and entrapment are not fighting to integrate hierarchy relations but instead may only be satisfied after the other is gone or dead.

In an important sense, submission is a social distance-decreasing activity occurring within the vertical hierarchy dimension. This is interesting because hierarchy is based on the formation of social distance-increasing relations. Submission appears to ease vertical social tensions, reflecting the involvement of social attraction in integrating harmonious

Fig. 8.5. Fighting between dogs sharing the same household can be serious, with females showing a greater risk for such problems than males. Breed-specific tendencies may exert a predisposing influence. Even after several years of tolerant interaction, increased tension, flare-ups, and overt fights may break out. The injuries can be significant and costly. The Akita pictured lived with another female with whom she shared the house for several years. Both dogs sustained numerous lacerations and punctures to front legs, shoulders, and the neck.

social relations. Submission by the newcomer and reciprocated tolerance shown by the resident dog is a form of social reconciliation and fairness enabling the dogs to build a friendly relationship. Submission rituals, social attraction, and trust based on fair play appear to give rise to pluralistic ascendant and descendant relations organized around a default dominant-subordinate relationship formed between the resident dog and the newcomer. In the case of puppies and young dogs, friendly dynamics and trust are facilitated by the concentrated exchange of numerous playful transactions in accord with a principle of fairness. The number of transactions taking place during a play bout may correlate with a mutual motivation to integrate friendly relations, that is, provide a social attraction-repulsion index. During an average play bout, dozens of fair-play exchanges may take place in comparison to a mere handful of fair exchanges that might take place during the course of an average day. According to this hypothesis, what might be achieved in terms of social integration following one or two bouts of play might take weeks or months to achieve in the absence of play, if at all. The surprises and joy generated by energetic interaction with a fair coplayer may be cathected to the coplayer as an object of affection and pleasure, thereby increasing attraction and antagonizing social emotions incompatible with social integration. In addition, object-mediated play between the handler and the dogs can be used to facilitate improved inhibitory control via the command and countermand regulation (e.g., go/no go and all-stop inhibitory exercises) over object-chase sequences involving prized toys and throw-away items.

Interdog Aggression Within the Household

Because of the obvious dangers involved, dogs sharing the same home that fight are frequently isolated from one another. Although separation is an important precaution to take when the dogs are left alone, constant isolation in different parts of the home is not a solution and does not appear to improve their chances of restoring trust. Social isolation is often convenient and may be a useful measure to prevent fights for the short term, but as a long-term arrangement separating the dogs may only serve to increase estrangement, torque up aggressive tensions, and generally worsen the situation. Eventually, someone will forget or lose track of their whereabouts and allow the dogs to get together. If a decision is made to keep such dogs in the household—which is not always practical or wise—then both dogs should receive intensive basic obedience training, graduated exposure and response blocking, counterconditioning, and appropriate inhibitory conditioning (e.g., go/no-go, stop-change, and all-stop procedures) to reduce aggressive tensions and improve the owner's ability to interrupt escalating tensions before they reach the flash point of no return. Fighting that breaks out at times of increased excitement (e.g., owner homecomings, feeding times, and before opportunities to go outside) often benefit from intensive wait (go/no-go) and delay-of-gratification training. Building a virtue around waiting and taking turns to obtain attention, affection, and other rewards by following rules can be very helpful.

Training Recommendations

The assumption that dogs fight because of a failure to form a dominance hierarchy has led to a widespread practice of treating such problems by having the owner leverage one dog into a dominant role and the other into a subordinate role by means of owner-controlled rewards and preferential alliances. Whether such brokering strategies exert a significant effect on dominance relations has not been demonstrated in dogs; one might assume, however, that such recommendations are not likely to provide much help with dogs lacking social attraction. In the absence of social attraction, it is unlikely that dogs can submit (subordinate) or to accept submission (dominant) while forming conciliatory proxemic relations. Further, despite the appearance of being ethologically sensible, the hypothesis requires a considerable leap of faith to assume that coherent and stable dom-

inant-subordinate relations might be telegraphed by means of owner leveraging and refereeing. Stable dominance relations appear to be dyadic in nature, requiring that one dog, the dominant, assert dominance and, in turn, accept submission from another dog, the subordinate, in order for them to integrate a friendly relationship. If the dominant dog fails to compel the subordinate to submit or is unwilling to accept the subordinate's offer of submission, there is no hierarchy relationship integrated between them. Training procedures aimed at integrating a social hierarchy by means of proxy seem especially problematic and ill-fated for dogs operating under the influence of mutual repulsion and dispersive tensions. In general, attempting to integrate power and hierarchy relations in the absence of mutual attraction results in social ambivalence (anxiety and distrust) and an ISS, whereas the integration of hierarchy relations under the influence of mutual attraction promotes affection, trust, and a VSS. According to this perspective, it is not only futile to establish hierarchy relations between dogs that are repulsed by one another, such efforts may actually worsen the situation. Instead of worry about which dog is dominant or not, the focus of training should be to leverage owner control over both dogs in a way that facilitates voluntary subordination and engenders confidence that the owner has the situation in hand. A strong and evenhanded owner presence provides a sense of security that may help the dogs to relax and feel safe, and thereby facilitates the activation of the SES.

To enhance owner control, both dogs are kept on leash at all times when under supervision. In all potentially provocative situations, efforts are taken to mediate nonprovocative access and sharing of appetitive and social rewards in a pluralistic way that supports cooperation and acknowledges social codes based on fair play, mutual attraction, and adherence to owner rules. The right of first possession is especially important with regard to competitive situations developing around attention-seeking behavior toward the owner, especially in situations where fighting has broken out in association with such activities in the past. Socially intolerant dogs that engage in excited jostling for proximity with the owner during greeting frenzies may incidentally enter proxemic zones inappropriate to their level of social attraction and as a result trigger a rapid escalation of arousal, possibly setting off an all-out fight. To prevent such situations in the future, precautions need to be taken to prevent close contact between the dogs during greetings, at least until they have integrated more friendly relations. During greetings, and at other times as well, interaction between the owner and dogs is formalized with rules of access that the owner dictates without respect to the rank of the dogs. Both dogs are discouraged from crowding and jostling with each other for owner attention. The owner should become a source of social control and order rather than attempt to broker dominant status or play the role of a referee between the dogs.

When left alone, such dogs should be separated, perhaps by keeping them in crates. Upon entering the house, the owner should give the dogs a few minutes to calm down before greeting them one by one. During such homecoming activities, the dogs are both put through a series of basic obedience modules and routines until attention and impulse control are fully established. The focus of work is directed toward establishing limits on pulling and stay/wait training. If warranted for safety purposes, the first dog is restrained at a tie-out station, while the second dog is leashed and greeted in a similar fashion. Dogs that exhibit tensions around feeding should be fed in separate rooms or crates. During food preparations, the dogs can be placed in separate rooms, crates, or tethered, where they should remain until both have finished eating and the food bowls have been taken up. When going outdoors for walks or coming back inside the house, the owner should determine the order of egress. Since squabbles and fights often develop around transition points involving excitement, the rules and rights of egression should be the focus of significant training and inhibitory conditioning until both dogs have learned to "Wait" and "Back" on signal. When giving treats or toys, the owner should determine which dog gets its share first, not based on a perception of

rank but based on compliance to command. If aggression tensions have occurred on furniture or beds, both dogs should be trained to stay off such items, unless invited up, and to obey rapidly when prompted to get off.

Dogs with fighting problems should receive intensive attention and impulse-control training, ICT, and inhibitory conditioning using the procedures previously described in Part 1, with both dogs learning to defer without hesitation to owner demands and directives. When agonistic tensions escalate and necessitate intervention, the owner should establish control without taking sides or worrying too much about which dog is dominant or how the limit-setting actions in the present might affect dominance relations between the dogs later. Social dominance is of little consequence in the beginning and, in any case, hierarchy relations will naturally take shape as social attraction and trust build between the dogs. If the dogs cannot tolerate being in the same room with each other, dominance relations are moot. In the long run, the social status of the dogs is far less important than preventing fights and providing a social space for promoting social attraction. Dogs given a sufficient number of safe opportunities to interact with each other may gradually acquire the necessary social attraction, confidence, and trust needed to integrate friendly relations. However, dogs that are pressured to integrate hierarchical relations in the absence of social attraction will only become progressively avoidant, intolerant, and reactive. When dogs possess adequate social attraction to give and accept submission, the establishment of default hierarchy relations naturally follows without much consequence. Only when the relationship is conflicted with repulsion and entrapment dynamics does dominance become a central point of concern and tension.

A social space conducive to social attraction and friendly interaction is established by setting limits on intrusive behavior and provocative exchanges. The training of an effective all-stop inhibitory response is of immense utility for controlling dogs in such situations. Both dogs are required to defer to the same basic imperative: fighting is not an option. Since fighting will only serve to sharpen animosities and promote social repulsion, when a fight is in the suspense phase every effort is applied to exert decisive inhibitory control, leaving no doubt or wiggle room concerning the handler's position on the matter. Nagging reprimands, ineffectual leash grabbing, fussing, and bribing will only ripen the problem, whereas an appropriately firm reprimand originating from the belly and delivered with force, a directive or saccadic leash prompt, or a brief electrical pulse can effectively interrupt and discourage the escalation of such behavior. Electrical training procedures can be useful for interrupting the preparatory phase, but once a fight has commenced, the use of electrical stimulation may only intensify reactive arousal and potentially worsen the problem. The goal is to take control and prevent the fight, not to referee or direct the ongoing drama and suspense between the dogs. The idea is to end fighting, not to explore dominance theories. Since the owner is more likely to possess sufficient social attraction to integrate a dyadic hierarchy with the dogs, it is the owner's dominance that most needs clarification in the process of establishing limits and order conducive to friendly relations between the dogs. A strong and fair owner presence appears to go a long way toward decreasing agonistic tensions between dogs, perhaps by helping them to feel safer while in the owner's presence and by using their attraction toward the owner to integrate submissive behavior and enhanced impulse control.

Transitional situations that stimulate a high level of excitement (e.g., going through doors) are particularly risky. In addition to taking steps to reduce excitement at such times, basic training and inhibitory conditioning are performed to establish and enforce appropriate rules and behaviors to reduce competitive tensions and to keep the dogs apart. Both dogs need to regulate interactive exchanges around valued resources and activities in accordance with a "first come, first serve" rule, to actively defer to the owner's directive authority, and to exercise preemptive restraint over aggressive impulses. Along with reward-based procedures, time-out offers a

means both to discourage inappropriate behavior and to reduce autonomic arousal and excitability. Anticipatory agonistic arousal and intention behaviors should be carefully monitored and diverted or disrupted before they intensify into overt threats. Prompting competitors to perform basic obedience modules and routines while in the presence of each other may be beneficial. Such activities provide a structure of rewards and owner approval conducive to cooperative interaction and fairness that may help to reduce agonistic tensions. The interactive benefits of such training may be especially beneficial if the response of the worker results in a reward matching the standard expectancy (SE) while the observer is given a reward that exceeds the SE for merely being present and not interfering. Alternatively, having the worker perform some basic exercise, but giving the immediate reward matching the SE to the observer and then giving the worker a reward exceeding the SE (surprise), may also promote constructive dynamics. Variations on this plan include surprises for the observer that result from interaction between the owner and the worker. For example, after prompting the newcomer to sit or lie down, the observer is prompted to orient by smooch or squeak, whereupon the orienting response is immediately bridged and the dog tossed a reward. Every so often, a surprise (high-quality reward or toy) is delivered, perhaps in association with showing added attention to the worker in the context of object-mediated play. The observer should be tethered in the beginning but can become increasing involved by means of an active-control line.

Organizing training activities so that surprise is arranged to occur as the result of cooperative interaction in various social situations can help to facilitate social exploratory behavior and mutual tolerance and possibly set the stage for play. The goal is to teach the dogs to take turns and to cooperate in order to avoid inappropriate contact and aggressive arousal. Training both dogs to walk on leash without pulling promotes a number of significant benefits mediating positive change. For example, walking appears to exert a potent stress-reducing and counterconditioning effect, in addition to stimulating beneficial allelomimetic associations that may create a sense of pack affiliation. Walks, especially those in which the owner imposes effective limits on pulling, a rule that is fastidiously enforced, may enhance the dogs' perception of the owner as a source of control and order. Initially, the dogs may need to be controlled by separate handlers, but as things progress the owner should be able to walk the dogs in brace (not coupled), as appropriate and safe. During controlled walks, orienting responses, quick-sits, and sit-stays or down-stays should be frequently practiced and rewarded.

Preventing and Breaking Up a Dogfight

Breaking up dogfights is fraught with dangers. The catastrophic arousal supporting combative behavior is the result of an avalanche of neurobiological events that may precipitously lower aggression thresholds in response to interference and restraint, causing fighting dogs to redirect hard snaps toward anyone that may foolishly attempt to stand between them. Owners enacting a referee role toward evenly matched dogs seem to be particularly prone to this error in judgment during a fight, perhaps stemming in part from a perceived loss of authority that they may feel obliged to regain or as the result of a fear that the dogs will seriously injure one another. However, going up against claws and sharp teeth with soft human skin and bravado is not an action that either dog would likely expect from the brightest member of the pack. It is especially risky to reach for the head or neck of fighting dogs, since such sites are typically active targets for biting. The bites received by owners as the result of interfering are often severe. Hitting or kicking dogs while they are fighting may only serve to inflame animosities or result in a bite to hand or foot or possibly cause an unintentional injury to one of the dogs. Although dogs rarely kill one another, letting dogs fight until one subdues the other may result in a rapid and uncontrollable escalation of aggression, perhaps causing serious injuries and expensive veterinary treatments. The danger is increased when unevenly matched or strange dogs are let alone to fight

it out. The majority of dog fights are rather noisy and unskilled affairs that are more about getting out of the fight than winning it, making it fairly easy for an assertive person to break them up. In contrast, serious fights between experienced combatants are often much more quiet and focused on conserving energy and acquiring favorable bite holds. Dogs with a propensity to fight should be kept under appropriate muzzle or leash control at all times when they are around other dogs in order to help prevent fights and to provide safe means to separate them should a fight break out. When potentially aggressive dogs are left alone, they should either be crated or confined to separate rooms.

Some experts have suggested that shouting reprimands or yelling obedience commands like "Sit!" might stop dogfights. In practice, such vocal demands will likely go unheeded and may actually inflame the situation, especially if the fight is well under way. An assertive reprimand, startling noise, or sharp leash jerk might be sufficient to interrupt a fight before it begins, but once the fight is under way yelling loud commands typically does little good. Although an experienced trainer can often succeed in breaking up a fight by force of will and intimidation without being bitten or causing more harm, the average dog owner or handler is more likely to be bitten and should be discouraged from getting between fighting dogs or attempting to jerk them apart, a procedure that might cause more serious injuries to the dogs. Since restraining one dog while the other one is free to attack at will puts the restrained combatant at a significant disadvantage and increases its risk of sustaining injuries, whenever possible two people should work together to separate fighting dogs. Pulling the dogs steadily apart by leash without jerking them is frequently effective. When outdoors, a large bucket of water and hose should be kept ready for emergencies. When fighting breaks out, the bucket of water is splashed on the combatants, thereby often (but not always) dousing their enthusiasm for the fight. A hose delivering a forceful stream of water typically works better. Indoors, a large bath towel can be soaked in water and kept in a plastic bag for emergency use. The towel is thrown over the dogs, whereupon they can be more easily separated by leash. In addition, quart-sized plastic bottles containing club soda can be strategically placed around the house. Another method uses a modified carbon-dioxide pump to spray a disruptive blast of compressed air at the rear end or belly of the attacking dog to disrupt the fighting impulse.

As a serious fight develops, experienced fighters may take mutual bite holds where they periodically shake their heads to set deep puncture wounds or grind into the flesh of the other dog and refuse to let go. Assuming that both dogs are leashed, in some cases squirting club soda in the mouth and face of fighters can cause them to break their bite holds. In other cases a foamy shaving cream can be sprayed liberally on the nose and mouth of aggressors to help loosen bites before pulling them apart by leash. A highly effective alternative employs two or three aromatic ammonia inhalers that are taped to the handle of a leash. After the inhalers are broken, they can be tangled near the nose of fighting dogs as they are pulled apart. The number of ammonia inhalers broken is determined by need, with the majority of dogs requiring that only one ampoule be crushed. Ammonia inhalers should not be presented by hand, because a dog may rapidly break its hold only to transfer the bite to the hand holding the ammonia inhaler.

When dogs fight off leash, separating them is considerably more complicated and risky. Despite opinions to the contrary, lifting a dog by its tail or hind legs does not reliably inhibit aggression or stop fighting. Grabbing fighting dogs by their rear legs or the base of their tails can work, but these are dangerous practices with large and highly aggressive dogs that risks evoking a redirected attack. The method requires two experienced handlers possessing sufficient strength to control the dogs properly after breaking up the fight to avert being bitten on the rebound. Also, dogs handled in such a way may twist and flail about and snap to break free only to race back and attack the other dog again. A better approach involves passing a leash around the dog's waist and then hooking the bolt snap

over the leash to form a noose. The noose is cinched up snugly and steady pressure is applied, lifting up and the pulling back until they let go. An alternative method used to set a waist noose involves passing the bolt snap through the handle of the leash. If a leash is not handy, a strong belt can be used instead. The foregoing method can be modified in situations where only one handler is available. A waist noose is applied to the more aggressive of two dogs, and both dogs are dragged to a place where the restrained dog can be safely tied off. A waist noose can now be applied to the second dog while various techniques are used to break the aggressor's bite (e.g., ammonia inhaler, club soda, shaving cream, compressed air, or breaking stick in the case of some fighting breeds) while the second dog is steadily pulled away. All bite wounds received by dogs during fights should receive veterinary treatment to prevent infection.

Repulsing the Approach of Threatening Dogs

Highly aggressive dogs should be muzzled or restrained on a muzzle-clamping halter when in public places. When performing exposure procedures in public, a risk always exists that another dog wandering around without supervision will approach the handler and dog. Every effort should be made to avoid such encounters and places where such situations might develop. Allowing an established aggressor to negotiate with a strange dog of unknown aggressive propensities poses a significant risk that might be penalized by the instigation of a fight and a significant setback in the dog's training. The approach of a potentially aggressive dog requires handler intervention to maintain a safe space between the approaching dog and the dog on leash. Preparation is crucial for effective prevention and control. When approached by a threatening dog, the handler should take account of all possible alternatives to direct confrontation, but given that the encounter is likely to occur, immediate precautions and preparations for decisive action should be taken. Keeping the dogs apart is usually far easier than breaking up a fight. The first step is to reinforce control over the dog by firmly grasping the leash with the left hand and setting a brake (see *Leash Handling* in Chapter 1). The remaining portion of the leash and handle is then tossed back over the right shoulder. The right hand should grasp the standing end of the leash just in front of the shoulder in preparation to swing the leash handle down forcefully, if necessary, to strike the approaching dog with enough force to turn it away.

In the case of an approaching dog that represents a limited menace, throwing a handful of treats in its direction can give the handler and his or her dog time to escape the situation. If the procedure works, it might need to be repeated several times to keep the other dog at a distance. In the case of a more persistent dog, a threatening step or two in the dog's direction, combined with a direct stare and shout ("Go Away!"), is often enough to cut short the adventure and cause the dog to veer away or to remain at a safe distance. If the dog ignores the warning and continues to approach with a threatening attitude, the handler might need to assert more forceful measures to deter its approach. Depending on the urgency of the situation, the handler might have enough time to first cast a forceful swing of the leash across the dog's path. This strategy, while kindhearted to the intruding dog, might complicate the situation and make it more difficult to ultimately control if the dog turns out to be looking for a fight. The deterrence of the warning flick may stop the dog from moving straight in, but not keep it from circling around to the rear or rushing in at the flank. Many dogs that get within close range can be deterred by a blast of compressed air. For ordinary purposes, a walking stick provides the best general defense against the threat of unsupervised dogs. The stick is used to jab at the aggressor in order to keep it at bay, not to pummel it.

SEX HORMONES AND INTRASPECIFIC AGGRESSION

Perinatal Distress, Androgenization, and Intrauterine Position Effects

Perinatal distress in association with obstetric complications has been shown to blunt pre-

frontal DA inhibitory transmission while at the same time increasing excitatory mesolimbic DA activity (Brake et al., 2000). Diminished medial prefrontal cortex (mPFC) activity appears to reduce an animal's ability to competently regulate subcortical activity, to optimize adaptive coping efforts, and to selectively focus attention and impulse control. Trauma during this critical period of biobehavioral integration may lay the groundwork for the development of various aberrant forms of impulsive behavior in predisposed dogs. The attention and impulse-control deficits, distractibility, and hyperactivity associated with birth-related distress may offer useful clues relevant to the etiology of canine hyperkinesis and other developmental behavior problems in dogs associated with exploitative obtrusiveness and social impulsivity.

A significant gender-related influence affecting the integration and attunement of autonomic control may stem from sexually dimorphic maturation rates. Among rats, DA fibers begin reaching prefrontal destinations earlier in the gestation period than 5-HT and NE fibers and continue to develop and proliferate later than them as well (Berger-Sweeney and Hohmann, 1997). Due to the influence of gonadal hormones, DA afferent pathways targeting executive control areas in the mPFC develop more rapidly in females than in males. These gender differences in the development of prefrontal DA pathways agree with developmental findings (Wilsson and Sundgren, 1998). At week 8, male and female puppies show clear maturational differences. Females are more active, spend more time exploring and less time in close proximity with the experimenter, and are more interested in objects than are male puppies. The delayed maturation of prefrontal DA pathways and mesocortical organization may confer an added vulnerability to environmental or social insults (Brake et al., 2000), perhaps adversely affecting the male puppy's ability to regulate emotion and impulse in adulthood. The canine PFC does not appear to reach full functional capacity until the end of the first year, marked by the emergence of object-permanence abilities and mature working memory (Gagnon and Dore, 1994).

Shortly before and after birth, a surge of gonadal testosterone enters the brain of male puppies, where it undergoes enzymatic conversion into hormonal derivatives that bind to androgen and estrogen receptors expressed in various target areas of the brain. The perinatal action of sex steroids on the brain predisposes dogs to express gender-appropriate social and reproductive behavior at puberty and adulthood. Among most animals, sex steroids play an active role in the organization of social hierarchy and territory via the development of species-typical patterns of agonistic and reproductive behavior. Sex hormones mediate numerous physiological, structural, and connectivity changes to serotonergic and other neural pathways that contribute to the regulation of mood, emotional reactivity, and aggression thresholds. Adverse prenatal and perinatal conditions may disturb the organization of androgen- and estrogen-responsive pathways, perhaps predisposing susceptible dogs to show lower reactive thresholds and impulsivity toward provocative social stressors in adulthood. The higher incidence of fighting problems among male dogs may be linked to perinatal androgenizing influences affecting the serotonergic system. For example, blockade of 5-HT_{1A} receptors during week 2 postpartum increases offensive aggression in adult intact rats, but a similar antagonist treatment failed to increase offensive aggression in female rats or male rats castrated on day 1 (Albonetti et al., 1996). In spontaneously hypertensive rats, an animal model of ADHD, early testosterone treatment has been shown to integrate a persistent HPA-axis dysfunction resulting in high ACTH levels and a blunted adrenocortical response (King et al., 2000)—a state of allostatic hypodrive that may dysregulate the SAM system.

In addition to the behavioral effects of perinatal testosterone on the central nervous system of male dogs, in utero exposure to testosterone may alter reactive thresholds in adult female dogs (see *Perinatal Androgenization* in Volume 2, Chapter 7). Female fetuses may be androgenized in a number of physiological, morphological, and behavioral ways by the transfer of testosterone from males to adjacent females situated between them.

Intrauterine position effects have not been definitively demonstrated in dogs, but have been shown to exert a significant influence on aggressive behavior in a number of other species (Ryan and Vandenbergh, 2002). For example, female mice and pig fetuses situated between males initiate more fights than females situated between other females. Interestingly, males situated between other males appear to be more sensitive to the effects of testosterone at maturity. These findings may account for some of the individual differences shown by dogs in response to elevated pubertal testosterone activity and response to castration. Females situated between other females may be more adversely affected by prenatal stress, suggesting that intrauterine exposure to testosterone may have a protective effect. Exposure to excessive stress or lack of appropriate stimulation during this perinatal period may exert lasting changes in the organization of aggression-mediating circuits.

Castration and Hormonal Therapy

Since a hormonal factor is believed to play a role in the development of intermale aggression, castration is frequently recommended (see *Hormonal Influences* in Volume 2, Chapter 7). Surprisingly, the effects of castration on dog fighting have not been carefully studied or documented (see *Effects of Castration on Aggressive Behavior* in Volume 2, Chapter 6). Existent studies are confounded by methodological shortcomings and suffer from inadequate sample sizes from which to derive therapeutic conclusions. The most commonly cited study estimates that approximately 40% to 60% of intermale aggressors show a combination of short-term improvement (within 2 weeks) and long-term improvement (after 6 months) following surgery (Hopkins et al., 1976). What this improvement exactly means is not clarified. Unfortunately, the potential beneficial effects of castration are often exaggerated, causing great dissatisfaction when the procedure fails to produce the hoped-for relief. Even where significant change is evident, it is rarely dramatic and almost never complete, especially when an experienced dog fighter is involved.

Clearly, the effects of castration are variable, with some dogs experiencing little or no discernible benefit. The author's impression is that very few adult dogs give up fighting as the result of castration. A few owners have reported that their dog's fighting activity actually worsened after castration. A frequently overlooked benefit of neutering is the effect it appears to have on other dogs. The most commonly observed consequence of neutering is a decline in the frequency of challenges and attacks directed against the castrated dog by intact males. Intact dogs may find castrated or prepubertal dogs less attractive to fight or, perhaps, such dogs may simply transmit fewer provocative signals. At any rate, despite limitations and questionable efficacy, neutering should be considered in the case of serious fighting problems or in young dogs showing a heightened propensity for interdog aggression. Among rodents, castration appears to reduce 5-HT_{2A}-receptor densities in the frontal cortex and ventromedial hypothalamus (Zhang et al., 1999; Sumner and Fink, 2000). Although gonadal testosterone is entirely eliminated from a dog's bloodstream within the first 24 hours after surgery, the physiological and psychological benefits associated with neutering may take several weeks to months to develop fully. The effects of castration are sometimes augmented by the administration of progestins (see *Sex Hormones: Estrogen, Testosterone, and Progesterone* in Volume 2, Chapter 6), a problematic option that is occasionally used in cases unresponsive to castration alone (Hart and Eckstein, 1998). Male dogs treated with progestins may produce a confusing olfactory signature that short-circuits the aggressor's interests, perhaps making treated dogs less attractive as targets for attack. Also, dogs treated with progestins appear to be less interested in fighting. Progestin therapy is associated with several potential side effects that should be evaluated by the supervising veterinarian and carefully monitored.

Testosterone, Serotonin Therapy, and Intraspecific Aggression

Although the use of serotonergic medications for the control of interdog aggression is need-

ful of clinical evaluation and controlled trials, some preclinical evidence suggests that circulating testosterone might provide a permissive or facilitatory effect on serotonin therapy. For example, the aggression inhibiting effects of 5-HT_{1A}- and 5-HT_{1B}-receptor agonists appear to depend on the permissive influence of androgens (Cologer-Clifford et al., 1999), suggesting the possibility that the therapeutic benefits of serotonergic agents for the treatment of dog fighting may be facilitated by the presence of circulating testosterone. Support for this hypothesis is provided by a study in vervet monkeys that evaluated the behavioral effects of three medications known to increase 5-HT activity by different mechanisms (Raleigh et al., 1985). Fluoxetine, quipazine (a 5-$HT_{1/2}$-receptor agonist), and tryptophan were given to dominant and subordinate monkeys. The researchers found that dominant individuals respond to 5-HT-enhancing therapies in a more robust manner than did subordinates. An increase in several prosocial behaviors attributed to the effects of enhanced 5-HT activity was also correlated with social dominance, including increased social approach, grooming, resting, eating, and huddling. Increased huddling was found to be a behavior produced only by fluoxetine. Dominant individuals also showed a greater reduction in negative behaviors, such as social avoidance, vigilance, and solitariness. The various 5-HT treatment regimens promoted a general calming effect and increased sociability—an effect that was especially prominent in dominant monkeys. Dominant individuals often exhibit higher levels of circulating testosterone, as well as other status-linked hormonal differences associated with HPA-system tone and gender-related agonistic behavior. For example, AVP appears to play a major role in forming hierarchical relations and territory (Ferris et al., 1986) and mobilizing power-dominance motivations (Sewards and Sewards, 2003). AVP-mediated aggressive behavior among hamsters is testosterone dependent (Delville et al., 1996). Ferris and colleagues (1997) found that fluoxetine inhibits gender-related offensive aggression in hamsters by antagonizing the action of AVP in the hypothalamus via 5-HT_{1A} receptors. These reports emphasize the close interaction among AVP, testosterone, and 5-HT in the regulation of agonistic behavior. Most dogs showing serious intraspecific aggression problems are routinely castrated prior to drug-therapy initiation. Given the aforementioned findings, the absence of circulating testosterone might reduce the efficacy of selective serotonin (5-HT) reuptake inhibitor (SSRI) medications such as fluoxetine for controlling gender-related intraspecific aggression. The foregoing data also suggest that aggressive dogs left intact during fluoxetine therapy might respond better to treatment. For previously castrated dogs, combination treatments incorporating dehydroepiandrosterone (DHEA), the adrenocortical precursor to testosterone and estrogen, with a compatible SSRI might prove useful (Wolkowitz et al., 1999).

Aggression Toward Cats in the Household

A common aggression problem involves dogs that chase or attack cats living in the same household. Once established, the urge to stalk and chase or attack cats can be highly resistant to behavioral change. Dogs that show a propensity to attack and injure or kill cats represent a significant risk, and they (or the cats) should be removed from the home. In other cases, dogs that lack appropriate training and socialization with cats may engage in playful chase escapades that cause the target cat significant distress. Often cats exposed to an aggressive or playful dog may remain in a part of the house that is inaccessible to the dog and only occasionally come out of hiding. Dogs prone to chase cats should be exposed to remedial socialization, reward-based integrated compliance training, and appropriate inhibitory all-stop conditioning aimed at suppressing the chase impulse. Most cases involving such behavior can be managed successfully by using a combined approach of exposure-habituation, response prevention, and graduated counterconditioning.

Getting the dog accustomed to being around the cat without evoking a chase response is best achieved by habituating the

cat to a wire carrier. Attempting to restrain a cat by leashing it with a harness or collar is highly problematic and can result in serious scratch and bite injuries to the handler. Carrier confinement allows the dog to approach the cat safely while minimizing undesirable behavior. The cat and dog are exposed to graduated counterconditioning under diverse circumstances. The leashed dog is progressively moved toward the confined cat while being fed a highly valued food item. One technique involves coating a wooden spoon with peanut butter and allowing the dog to lick from it as it approaches the cat in stages without becoming reactive. The cat should also be fed a highly prized treat (e.g., puréed tuna) through the carrier by a helper. A muzzle-clamping halter or muzzle can be used to help discourage lunging and barking. Incorporating brief exclusionary TO with DRO training can also reduce such behavior. In cases not sufficiently responsive to the foregoing training efforts, remote electronic training can be used to entrain potent inhibitory control over chasing behavior. Internal electronic containment can be used to reinforce such training, but such devices are far from foolproof, and under the excitement of the chase the dog may run through the field and attack the cat. Dogs with a history of chasing cats should either be crated or be confined to a safe room when left alone. A device that could be helpful for controlling undesirable canine behavior around cats would involve a small medallion worn by the cat. If the cat is approached within a certain critical distance, a receiver device worn by the dog is activated that delivers an appropriate warning and aversive stimulus of sufficient strength to cause the dog to avoid the cat.

Biobehavioral Monitoring and Electronic Control of Behavior

PART 1: MONITORING AUTONOMIC AND EMOTIONAL STATES

STRESS, TEMPERATURE, AND BEHAVIOR

In addition to preparing dogs for physical exertion and emergency action, the sympathetic nervous system mediates physiological changes associated with thermoregulatory control that closely parallel the preparatory arousal associated with fear and anger. Thermoregulatory adaptations for coping with thermogenic changes appear to have been recruited and incorporated into systems evolved to cope with emotional stressors (e.g., decreased/increased activity, vascular dilation/constriction, panting, sweating, shivering, and piloerection). The close relationship between physiological changes associated with thermoregulation and sympathetic arousal suggests an interesting potential relationship between reactive emotional states and increased thermogenesis. The persistent panting and excessive salivation exhibited by some separation-reactive and separation-distressed hyperactive dogs may reflect a shift in energy metabolism and thermogenesis resulting from reactive states triggered by the loss of social contact or control over significant events. The reactive relationship between separation distress and increased thermoregulatory activity suggests an interesting developmental hypothesis; namely, the contact dynamics between neonatal puppies while mediating mutual thermoregulation may orchestrate the expression of neurobiological substrates that anticipate the later emergence of social attraction and attachment behavior, and the integration of competent regulation of sympathovagal arousal and impulse control. According to this hypothesis, early stressors and insults affecting canine thermoregulatory capacity may exert far-reaching effects on the organization of sympathetic regulatory networks needed to competently modulate reactive thresholds controlling separation distress and flight-fight behavior. These reactive propensities may be partially revealed by the size of differences between basal body temperatures and temperatures obtained after exposing the dog to provocative stimulation. In addition to early developmental insults, thermogenesis and compensatory thermoregulatory changes appear to be strongly influenced by individual genetic differences. Corson and colleagues (1973), for example, found that dogs differentiate along two general lines in the way they cope with exposure to uncontrollable aversive stimulation. The first group, referred to as *anti-diuretic* types, shows a quintet of reactive physiological changes: tachycardia, persistent hyperpnea, excessive salivation, and increased secretion of vasopressin. The researchers hypothesized that these sympathetic changes were a reactive pattern of compensatory thermoregulation in response to a reactive increase in energy metabolism and thermogenesis. Other dogs, referred to as *diuretic* types, responded to the same uncontrollable stimulation in a less global and reactive way, showing a greater capacity to adapt, consistent with a well-developed flirt-and-forbear anti-stress system. These findings suggest the possibility that temperament differences affecting a dog's relative ability to cope with provocative stimuli may be revealed and indexed by the size of temperature changes evoked by uncontrollable threats and challenges.

Although the significance of core temperature to temperament in dogs remains to be worked out in detail, body temperature appears to provide a sensitive index of psychological distress and stress in laboratory rodents. Stress-induced hyperthermia is associated with anticipatory anxiety and increased glucocorticoid activity (Groenink et al., 1994). Exposure to social conflict can produce durable changes in daily temperature patterns, depending on whether the animal accepts defeat or fights back (see Meerlo et al., 1996 and 1999). Other research has shown that temperature changes are particularly sensitive to psychological stressors as opposed to physical ones. Long-term temperature changes can occur in association with the psychological distress from being in the same compartment with conspecifics receiving daily sessions of shock delivered every 60 seconds for an hour over 12 weeks. Distressed bystander rats showed a long-term elevation in temperature, with a 0.20°C elevation in

temperature after a 2- to 3-month rest period (Endo and Shiraki, 2000). Among rats, temperature change appears to index contextual fear conditioning, perhaps warranting validation in dogs (see Godsil et al., 2000). These findings suggest that tracking temperature changes might be a useful noninvasive tool for assessing psychological distress in dogs.

Functional Lateralization and Tympanic Temperature

Some lines of research have formed around the significance of tympanic temperature differences between the ears as measured by infrared tympanic thermometers. These temperature differences may be due to lateralized cortical functions, with right-side prefrontal asymmetries associated with the behavioral inhibition system (BIS), negative emotion, inhibition, hesitation, stress regulation, defensive behavior, anxious arousal, and passive modal strategies, whereas left-side prefrontal asymmetries appear to be associated with the behavioral approach system (BAS), positive emotion and arousal, curiosity, surprise, joy, exploration, offensive behavior and trait anger (Harmon-Jones and Sigelman, 2001), and active modal strategies. Anger generating positive affect, arousal, confidence, struggle, conquest, and power appears to be integrated by the BAS (see Harmon-Jones, 2003), whereas the BIS integrates negative affect, anxiety, disappointment, resentment, defeat, and failure. According to this hypothesis, both the BAS and the BIS play a role in representing different functional and motivational aspects of anger and anxiety.

In conjunction with executive functions, the prefrontal cortex (PFC) appears to index and modulate allostatic load via hypothalamic-pituitary-adrenal (HPA)-system regulation (Diorio et al., 1993)—a function performed chiefly by the right medial PFC (Sullivan and Gratton, 1999). The frontal area via the anterior cingulate cortex (ACC) also figures prominently in the integration of attention shifting, emotional processing, and the corticovisceral regulation of sympathovagal tone (Thayer and Lane, 2000). Consistent with the lateralization of cognitive functions, the orienting response of a dog to a click or the presentation of food following a conditioned stimulus evokes increased electroencephalogram (EEG) activity in the left cerebral hemisphere, whereas once the orienting response to the click is extinguished, the click stimulus tends to increase activity in the right hemisphere (Simonov et al., 1995). While processing novel auditory and visual stimuli, left lateralization appears to predominate, but, as the conditioned response is well established, asymmetry is either absent or shifts to the right hemisphere (Preobrazhenskaia, 2000).

In general, right hemisphere specializations are organized to cope with defensive demands and threats evoking withdrawal and behavioral inhibition, whereas left lateral hemisphere adaptations are closely tied to approach, behavioral activation, challenging situations, and heightened appetitive drive states. The right hemisphere appears to promote withdrawal, anxious arousal, and activation of the HPA system (Wittling and Pfluger, 1990). When the provocative event is uncontrollable, cortisol levels may dramatically increase along with a heighten risk for defensive or reactive aggression in predisposed dogs. In contrast, increased left frontal activity tends to be associated with positively valenced states of arousal promoting approach, power, and potential for offensive or impulsive aggression. In contrast to the increased cortisol levels observed in association with right hemisphere stimulation, left hemisphere activation in response to emotionally aversive stimuli tends to suppress salivary cortisol secretion (Wittling and Pfluger, 1990), a finding consistent with a hypothesized linkage between low cortisol levels and impulsive aggression.

Lateral shifting of cortical activity appears to anticipate changes in brain metabolism rates and vascular flow to the left and right sides of the brain, depending on the processing being performed. These metabolic and vascular changes appear to be reflected in rapid changes in temperature. Among chimpanzees, for example, observing a video recording of severe aggression results in elevated right-ear tympanic temperature,

whereas observing neutral images or images of playful activity does not alter baseline temperatures (Parr and Hopkins, 2000). When engaged in visual cognitive tasks, chimpanzees show an opposite pattern of neurothermal lateralization, with left-ear temperatures increasing and right-ear temperatures decreasing (Hopkins and Fowler, 1998). Several studies have shown that human impulsive aggressors exhibit increased subcortical arousal, together with reduced right and left prefrontal activity (see Raine et al., 1997 and 1998), suggesting that impulsive aggression may be associated with reduced executive function and regulatory control over subcortical emotional states and aggressive impulses. Children with intractable partial epilepsy presenting comorbidly with impulsive aggression show temporal and bilateral medial PFC (mPFC) hypometabolism (Juhasz et al., 2001). Maximal differences in cerebral glucose metabolism were found in the right and left middle temporal gyrus in comparison to nonaggressive children with epilepsy. The foregoing is consistent with the notion that the right hemisphere might play a predominant role in the representation and modulation of excitatory sympathetic arousal mediating rapid behavioral adjustments to emotionally provocative threats and uncertainty (Wittling, 1990; Wittling et al., 1998b), whereas the left hemisphere is more directly involved in the modulation of parasympathetic pathways in association with emotional arousal mediating social coping and control strategies (Wittling et al, 1998a). In combination, left and right hemispheres exercise profound autonomic attunement and integrative influences over blood pressure, heart rate, and HPA-system activity.

Paw Preference, Laterality, and Tympanic Thermal Asymmetry

Tan (1987) has reported that more dogs exhibit a right-paw preference (57.1%) than a left-paw preference (17.9%), with 25% being ambidextrous (N = 28, 19 females and 9 males). Wells (2003) has shown that the lateralized preference for paw use is probably gender related in dogs, with females appearing to show a right-paw preference and male dogs tending to show a left-paw preference. However, Wells' findings concerning paw preference are possibly confounded by an uncontrolled influence of previous training, at least with respect to one of the tasks used to evaluate handedness (i.e., giving a paw). More recently, though, Quaranta and colleagues (2004) have reported additional data concerning the lateralization of paw preference that appears to support Wells' gender hypothesis. They also report evidence suggesting that paw-use lateralization is correlated with various immune functions; however, these immune differences are not correlated with gender. Since dogs show evidence of cerebral asymmetry, with the right hemisphere tending to be significantly heavier and larger than the left in most dogs (Tan and Caliskan, 1987a and b), one might suppose that paw preference is related to morphological asymmetry, but Tan could not establish a correlation between brain morphology and a specific paw preference in dogs. The larger mass and area comprising the right hemisphere suggests that the right side of the brain should be associated with increased metabolic activity and blood flow in association with right cerebral dominance. Research on paw preference in rodents introduces an interesting dimension to this hypothesis. As in dogs, the right hemisphere of rats tends to be larger than the left. In addition, rats exhibit a pattern of neurothermal asymmetry that is correlated with paw-use preference (Klimenko, 2000), but the temperature gradient between left and right hemispheres is most conspicuous in left-handed rats and least so in right-handed rats; ambidextrous rats show an intermediate thermal gradient. These various differences affecting interhemisphere thermal gradients appear to be ontogenetically stable (Klimenko, 2001). Temperature kinetics on the surface of the cerebrum that have been imaged in rats (Shevelev et al., 1986) indicate relatively rapid left-right and right-left hemispheric asymmetries and crossover patterns of movement and equilibrium. The stability of interhemisphere thermal gradients from an early age raises the possibility that tympanic temperature might be of value in identifying temperament traits

and coping styles early in life. Further, given the findings reported by Quaranta and colleagues in dogs and numerous studies in rodents linking behavioral lateralization and neural asymmetries to immune reactivity (Fu et al., 2003) and HPA-system activation (Neveu and Moya, 1997), both aspects of adaptation may be correlated with tympanic thermal asymmetries and changes in bodily temperature associated with stress and sickness. Rodents showing a right-paw preference appear to be more vulnerable to physical and behavioral stressors (Neveu et al., 1998), whereas those exhibiting a left-paw preference may be more prone to immune disorders (Fu et al., 2003). Consequently, it would be of interest to learn whether the basal intertympanic thermal gradient is a good predictor of paw-use preferences in dogs.

Measuring Tympanic Temperature

Thermal scanners can be used to rapidly (in 1 second) and accurately measure tympanic temperatures from a dog's ear. Whenever possible, at least three readings from each ear should be taken and a mean score assigned. Tympanic thermal asymmetries may possess value as novel endophenotypes identifying temperament traits and coping styles, as appears to be the case among children (Boyce et al., 2002) and various animal species. Tomaz and colleagues (2003), for example, have reported that marmosets exhibit asymmetrical tympanic temperature shifts consistent with a right brain specialization for coping with capture/restraint stress and fear. Monkeys that have been repeatedly captured show a significant reduction in tympanic temperatures on the right side. A similar effect appears to occur in some dogs. For example, temperature readings from a nonaggressive but emotionally reactive Labrador retriever (5-year-old neutered male), which responded with vigorous escape arousal associated with restraint, initially showed a left-right asymmetry (left ear, 102.1°F; and right ear, 100.6°F). However, after the struggling ceased, a slightly opposite right-left asymmetry (left ear, 101.5°F; and right ear, 102.0°F) emerged that was followed by a gradual temperature decrease and left-right equilibrium in association with comforting talk and massage (left ear, 100.6°F; and right ear, 100.3°F).

Some preliminary data suggest that dogs exhibiting canine impulsive aggression may show lateralized tympanic temperature variations consistent with the foregoing hypothesis. For example, a male Wheaton terrier (neutered 3-year-old) with a history of threatening and biting strangers and familiar visitors showed an initial increase in temperature in the left ear in association with the ringing of a doorbell plus greeting (left ear, 99.1°F; and right ear, 98.0°F). A follow-up reading taken after the trainer had been in the house for approximately 1 hour showed that the temperature range had not significantly changed but that the asymmetry had shifted from the left to the right ear (left ear, 98.7°F; and right ear, 99.4°F). The initial higher left-ear temperature may reflect an increase in glucose metabolism or a change in regional blood flow to the left side of the brain in response to the sudden change and the excitement triggered by the unexpected visit. The relatively low temperatures in response to the doorbell is a bit surprising, however, since the dog was highly agitated and aggressive (e.g., strong threat barking, lunging, and vigilant readiness)—behavior that one might expect to elevate temperature. The presence of a low basal cortical temperature is consistent with increased regional blood flow. Cerebral blood flow in dogs appears to be autoregulated by means of metabolic signals, consistent with the idea that the lower temperature may reflect a rapid increase in arterial flow of blood to the left or right side of the brain.

In another case, a female Saint Bernard (spayed 1-year-old) that showed hyperactivity and extreme delay-of-gratification deficits, intrafamilial agonism, and social control/frustration intolerance from an early age onward toward one particular male family member exhibited an unusual pattern of tympanic asymmetries and temperature fluctuations consistent with decreased cerebral metabolic activity or pronounced cerebral blood-flow changes. In contrast to the pattern of impulsivity exhibited by the aforementioned Wheaton, the Saint Bernard exhibited a pat-

tern of intrusive hyperexcitability and exploitive behavior toward visitors. Tympanic temperatures taken 15 to 20 minutes after arriving at the home indicated a right-left asymmetry (left ear, 100.4°F; and right ear, 102.0°F). After a long walk, tympanic temperatures were taken again. Interestingly, as the family member who was the prime target of aggression approached to help restrain the dog during the scanning procedure, the dog's temperature plunged bilaterally (left ear, 95.2°F; and right ear, 95.3°F). Since these measurements seemed oddly low, a second measurement was taken that confirmed a significant hypothermic event (left ear, 96.6°F; and right ear, 97.1°F). The dog's tympanic temperatures continued to move in the direction of normothermia and an opposite left-right asymmetry as it calmed (left ear, 101.4°F; and right ear, 100.3°F).

CARDIOVASCULAR ACTIVITY AND EMOTIONAL BEHAVIOR

Early factor analyses found that various cardiovascular patterns loaded with certain emotional variables and temperament traits in dogs (Royce, 1955; Brace, 1962; Scott and Fuller, 1965; Cattell and Korth, 1973). Royce's work, in particular, points intriguingly toward a potential link between temperament, heart rate, vagal tone, and emotional tendencies predisposing a dog toward reactive behavior. For example, he found that heart-rate changes in response to divergent social stimuli, including potent vagal braking effects in response to both calming and threatening vocal control efforts, loaded with an increased tendency toward behavioral reactivity. Royce describes an aggression factor that occurs with impulsiveness and a deceleration in heart rate in response to electric shock. Vagal braking in response to both shock and a threatening voice is also associated with an unidentified trait consisting of attraction, dominance, and temperature variables. Royce also found that dogs showing an increased propensity for behavioral reactivity exhibit a rapid sympathetic acceleration in heart rate in response to muzzling restraint, but showed no change in heart rate when administered an electric shock.

Heart Rate

Among laboratory dogs, Beerda and colleagues (1998) reported a nonspecific increase in heart rate in response to both social and nonsocial stressors, concluding that "heart rate increases should best be regarded as general responses to possibly meaningful events, irrespective of whether these are appreciated as positive or negative" (378). Although these researchers could not demonstrate the existence of discriminative heart-rate changes in response to acute social and nonsocial stressors, they did show differences in the HPA activity of dogs exposed to nonsocial stressors (e.g., loud sound, electric shocks, and a falling bag) versus dogs exposed to social restraint and startle delivered by a social object. Whereas nonsocial fear-eliciting stimuli increased cortisol release, startling events (repeatedly opening an umbrella in the dog's direction) and mechanically forcing the dog down to the floor by pulling up on a rope passed under a bar fixed to the floor or by shoving it down by hand and holding it there for 20 seconds (restraint) did not increase cortisol release. The steady pulling and manhandling procedure was performed twice with a 20-second interval between each trial. All of the social procedures were performed with the experimenter wearing a mask, hat, and coat scented with an unfamiliar odor. Despite the directive challenge, risk, and novelty of such stimulation, no significant increase in cortisol activity was observed. The absence of stress in response to restraint (defeat) is opposite to the robust and long-lasting effects that novelty and social defeat have on other species tested under laboratory conditions (see Koolhaas et al., 1997). The increased submissive precursor behaviors exhibited by challenged dogs (e.g., oral activities, paw lifting, slightly lower body posture, changes in ear position, and other signs of submission) appear to reflect a standing readiness to submit mediated by an effect of person. This hypothesis is consistent with a specialized flirt-and-forbear antistress system and enhanced parasympathetic capacities that enable dogs to cope with challenges and risks in a nonstressful manner, whereby the HPA system remains relatively unperturbed even though a dog shows various submissive pre-

cursors. In the absence of the flirt-and-forbear antistress system (e.g., socialized wolves), similar social challenges and threats would likely cause stressful flight-or-fight reactions and the activation of HPA system.

Recently, King and colleagues (2003) have suggested that heart rate might be a more practical and sensitive measure of a dog's reactivity to novelty and fear than are cortisol levels. Other researchers have found that a reactive pattern of cardiac acceleration and deceleration in response to social and environmental stressors appears to correlate with an increased vulnerability to reactive social behavior and stress proneness (Vincent and Michell, 1996; Vincent and Leahy, 1997) (see *Autonomic Arousal, Heart Rate, and Aggression* in Chapter 6). Blood-pressure and heart-rate changes appear to be highly sensitive to traumatic events, and conditioned cardiovascular changes may persist (schizokinesis) or worsen (autokinesis) long after the overt escape/avoidance behavior has ceased (Dykman and Gantt, 1997).

The evolution of specialized flirt-and-forbear antistress capacities has given dogs relatively sophisticated capacities for maintaining sympathovagal balance and HPA-system stability via the integration of an adaptive coping style in the context of forming secure attachments. The integrated and refined attention and impulse control resulting from adaptive learning and the vagal-mediated attunement of autonomic control systems reguates increases or decreases of heart rate in anticipation of expected needs, motivational changes that enable dogs to cope with social challenges and risks without becoming overly stressed by them. The failure of earlier work (Beerda et al., 1998) to detect a differentiation of heart rate in response to different stressors might be understood within the context of these adaptive specializations evolved by dogs to cope with domestic life. Accordingly, companion or service dogs (see Vincent and Leahy, 1997) reared under the influence of consistent and enriched home or training environments may express autonomic elaborations and complex attunement dynamics while integrating an adaptive coping style that dogs living under the more austere and impoverished conditions of the laboratory do not acquire. In addition, rewarding exchanges that occur within the home setting appear to be necessary precursors for the activation of the social engagement system (SES), which, in turn, facilitates vagal-mediated secure social and place attachments.

Heart-rate Variability

Cardiac markers of sympathetic or parasympathetic tone may be useful for detecting disturbances affecting the SES. For example, sympathetically reactive wild rats exhibit dramatically more arrhythmic ventricular events (premature beats) and less parasympathetic rebound after defeat than do Wistar rats, a strain that is more sociable and less reactive to novel social stimuli and showing increased heart-rate variability and marked vagal recruitment following defeat stress (Sgoifa et al., 1998). In another study, Sgoifa and colleagues (1999) found that wild rats also exhibit significant differences in the way they respond to social versus nonsocial stressors, with wild rats showing more ventricular arrhythmias and sympathetic dominance after social stress than after nonsocial stress (restraint).

Dogs appear to produce a comparatively greater parasympathetic inhibition over cardiovascular activity than do humans (Little et al., 1999). When orienting toward novel stimuli, dogs show a rapid decrease in heart rate that continues while engaged in sustained attention or exploratory activities. A lower heart rate is also produced by a wide range of evoking social stimuli, including petting, muzzle holding, pinning, and holding in the arms, suggesting that parasympathetic motor systems may play an integral role in the integration of submission behaviors (Fox, 1978) and hierarchic relations (Sgoifa et al., 2001). Scott and Fuller (1965) observed that respiratory sinus arrhythmia (RSA) and heart rate are closely related among dogs, in that a slow heart rate is typically arrhythmic, whereas a fast heart rate is usually more regular and indicative of increased sympathetic tone. While lying down and resting, heart activity is prominently under the control of parasympa-

thetic tone, whereas, when standing, heart rate is a composite of sympathetic and parasympathetic components (Palazzolo et al., 1998). During emotionally exciting events, parasympathetic control is withdrawn, causing the heart rate to increase, whereas the reinstatement of parasympathetic control (vagal braking) by vocal reassurance or petting decreases heart rate while increasing heart-rate rhythm variability. As a result, measures of *heart-rate variability* (HRV)—that is, beat-to-beat changes in heart rate—appears to reflect the state of autonomic systems mediating behavioral adjustments and may be useful for evaluating the effects of stress on sympathovagal tone and reactive/impulsive adjustment (Pagani et al., 1986; Billman and Dujardin, 1990).

Hypothetically, dogs expressing relatively high tonic HRV measures might be expected to be more adaptable and to habituate more rapidly to social and environmental novelty and unexpected change, whereas dogs expressing reduced tonic HRV should tend to be more reactive and exhibit a nonhabituating orientation toward novelty and unexpected change. The normally reduced heart rate in response to environmental and social exploration may be diminished or unstable in such dogs, especially when exposed to unfamiliar situations or novel social targets. In addition, dogs exhibiting reactive arousal show variable amounts of plasma adrenal epinephrine and norepinephrine, depending on the relative contributions of anger and fear comprising the reactive state (Verrier and Dickerson, 1991), with epinephrine (fear) and norepinephrine (anger) representing potentially useful markers for assessing arousal and aggression risk. Dogs affected by anticipatory social anxiety may exhibit signs of persistent (nonhabituating) anxious or conflictive arousal in association with hypervigilance and readiness for defensive autoprotective behavior, changes that are correlated with heart rate, HRV, and other indicators of autonomic activation. Autonomic states associated with past anger or predisposing a dog to anger may be correlated with signature changes expressed in cardiovascular activity (see Kovach et al., 2001). As a result, cardiovascular data may provide valuable information relevant to a better understanding of the etiology and treatment of behavior problems associated with impulsivity and a reactive coping style.

As a result of social ambivalence, dispersive tensions, and chronic inhibitory strain, dogs may show signs of autonomic dysregulation in response to ambiguous or uncontrollable social stimuli or physical challenges. The relative stability of sympathovagal tone may be reflected in changes to heart rate and indexed by HRV following sensory and physical challenges (e.g., novelty, unexpected change, demands requiring sustained attention, exposure to provocative stimuli, unwelcome approach while in safe refuges, and pulling the dog by leash from a resting area). Conflict and emotional distress may contribute to the disruption of attention functions gradually impairing a dog's ability to competently engage and disengage selective attention. Social and attentional disengagement facilitate the loss of autonomic attunement, thereby significantly reducing the dog's ability to adjust arousal and to cope adaptively with changing environmental and social demands. Basic training appears to exert a beneficial influence on sympathovagal balance by improving vagal regulation over sympathetic shifts in response to novelty, handling, and restraint. Heart-rate deceleration is reliably evoked by petting dogs that respond to social tactile stimulation as a reward (Fonberg et al., 1981), perhaps contributing to the evident cognitive and emotional attunement that is brought about by the training and socialization process. Conditioned appetitive stimuli and behaviors trained in association with food reinforcement tend to promote parasympathetic balance and calming effects, as well.

The potent parasympathetic effects of stimuli anticipating the presentation of food on arousal was a central finding of Pavlov's work, with salivation being closely regulated by the parasympathetic branch of the autonomic nervous system. Among young horses, those having received training tend to be less emotionally reactive, showing a lower nonmotor heart rate and greater HRV than untrained horses (Visser et al., 2002). The adaptogenic benefits of basic training appear

to depend more on an ability to freely choose and act upon events that are relatively predictable and controllable rather than the motivational direction of the incentives prompting behavioral change (see Stichnoth, 2002). When a dog is physically immobilized, aversive events may be perceived as more threatening and conducive to the activation of autoprotective adjustments, whereas a dog that can move about freely may feel more in control, perhaps perceiving the event as being at least escapable, if not fully predictable or controllable.

Effects of Restraint and Immobilization

Many studies with diverse taxa have shown that inescapable physical restraint or the induction of cataleptiform immobility results in bradycardia, even cardiac arrest and sudden death in some cases. Richter (1957) found that wild rats held until they stopped struggling rapidly succumbed when placed into a vat of water, unlike nonstressed wild rats that continued swimming for 2 days or more. With a highly unstable dog, the mere presence of a person may trigger intense vagal braking and severe bradycardia. For example, Gantt and colleagues (1966) described a dog restrained in a Pavlovian harness whose heart rate moved from 140 to 180 bpm to as low as 20 bpm when exposed to a person standing nearby, and on several occasions this dog went into cardiac arrest for 6 to 8 seconds when petted.

A study by Reese and colleagues (1982) on the effects of physical restraint and petting on nervous and normal pointer dogs revealed intriguing behavioral and heart-rate differences in the way dogs cope with physical restraint. The dogs were restrained by turning them on their backs in a sling-restraint device. Once in the restraint sling, the dogs were calmed with stoking on the belly (1 stroke/second for a minute). After the induction phase, the dogs were left alone in the sling-restraining device during a 2-minute observation phase and watched from a separate room through a one-way mirror. Nervous pointers showed persistent cataleptiform immobility with bradycardia throughout the induction and observation phase and remained in the sling until they were tipped out of it. During a 5-minute postrestraint observation period, the nervous dogs showed a significant postrestraint sympathetic increase in heart-rate activity. In contrast, normal pointers show an initial tachycardia associated the induction phase, followed by postural and muscular relaxation, and a sustained postrestraint bradycardia as they move about after freeing themselves from the sling or upon being tipped out of the device. The normal dogs that remained in the sling after the induction period appeared relaxed and showed no head or neck immobility, and one of them even wagged its tail at the end of the 2-minute observation period. All of the nervous dogs had to be tipped out of the sling, whereupon they reflexively righted themselves and remained in an upright frozen posture during the 5-minute postrestraint period. Normal dogs that freed themselves from the sling during the 2-minute observation period exhibited more pronounced bradycardia scores (105 to 87 bpm) in comparison to normal dogs that remained in the sling (106 to 99 bpm) during the same period. The lower heart rates of the normal pointers that freed themselves may reflect parasympathetic relief associated with successful escape to freedom, whereas the sustained tachycardia of the nervous pointers may reflect increased anxious arousal associated with an escape from danger (see *Escape to Safety versus Escape from Danger* in Chapter 8).

Williams and colleagues (2003) have studied the effects of inescapable immobilization on the heart rate and HRV of a Great Dane. The dog was immobilized inside a wooden box that allowed it to stand with its head protruding from an opening in the front. Immobilization was achieved by filling the box with triple-cleaned oats until the dog's body was fully covered, allowing only its head to move about freely. To control head and neck movements, a short leash was attached to a flat collar and fastened to the front of the box. The dog was also fitted with a muzzle-clamping halter to control its head and jaws. Heart-rate and HRV data were collected by means of an ambulatory monitoring device. During a

pretest-baseline procedure, the dog was exposed to an unknown target dog to instigate aggressive arousal and establish baseline reactivity. The leashed dog showed strong reactive behavior (e.g., lunging, jumping, growling, and barking) and an elevated heart rate (160 bpm) toward the unknown dog in comparison to its response to a familiar dog (135 bpm) and no dog (111 bpm). Pretest HRVs in response to both the unknown and known dog were identical. After an hour of immobilization, the dog showed a significant decrease in heart rate (91 bpm) and an increase in HRV indicative of parasympathetic activation. During an exposure procedure in which the unknown dog was presented to the immobilized dog, first at 15 meters away and then gradually moved incrementally closer over 31 minutes, aggressive behavior was suppressed. During the postimmobilization tests, the dog "was not as reactive" toward the unknown dog and showed a decrease in heart rate together with a slight increase in HRV in comparison to preimmobilization scores. The reduced heart rate and slight increase in HRV at the end of the experiment toward the approach of an unknown dog might reflect parasympathetic relief associated with getting out of the box—a state of arousal incompatible with aggression.

Since bradycardia and alterations in HRV in dogs can be produced by a variety of procedures (e.g., petting and massage, pinning restraint, and tonic immobilization) producing a high or low level of physiological stress, future investigations should include other relevant autonomic arousal markers (e.g. catecholamine and cortisol levels) to help determine whether the immobilization procedure works by relaxing dogs or as the result of some other mechanism triggered by immobilization, fear, or loss of control (see *Stress-related Potentiation of the Flight-Fight System* in Chapter 6). In particular, many features of the procedure seem consistent with the learned-helplessness paradigm. Exposure to inescapable aversive stimulation while fully immobilized is a central feature of the learned-helplessness protocol (see *Stress, Traumatic Avoidance, and Laboratory Experiments with Shock*). Exposing a reactive dog to the slow approach of an unfamiliar dog (a social stimulus eliciting intense defensive arousal) in the manner described reminds one of being buried up to the neck in sand and then forced to watch the tide slowly come in without any means of defending oneself or escaping the encroaching threat. The induction of learned helplessness has been shown to reduce escape and avoidance behaviors and to exert potent antiaggression effects in dogs (Seligman, 1975) and rats (Maier et al., 1972), perhaps explaining the effect that the immobilization procedure is believed to have on defensive aggression in dogs (Williams and Borchelt, 2002).

The authors speculate that immobilizing restraint combined with "tactile pressure" might explain the observed changes in heart rate, HRV, and reduced aggression exhibited by the immobilized dog. They compare the immobilization procedure that they use with Grandin's squeeze machine (see *Taction and Posture-facilitated Relaxation* in Chapter 6) but overlook an essential difference: the person in the squeeze machine is not exposed to a threat slowly moving in their direction from which they cannot escape. While immobilization and "loss of control" procedures may temporarily reduce aggression, they may also adversely impact more desirable social behaviors and learning capacities that depend on voluntary initiative. Finally, in the case of highly reactive and unstable dogs or dogs with heart disorders, the stressful induction of pronounced fluctuations in heart rate by means of rapid exposure to an inescapable threat educing high levels of fear or anger under immobilizing restraint may pose a significant cardiovascular risk (Kovach et al., 2001; see Kamarck and Jennings, 1991).

Devices Used to Monitor Autonomic and Stress-related Changes

Although HRV may ultimately provide the most useful diagnostic information with respect to linking behavior problems with autonomic tone and sympathovagal imbalance, such equipment is relatively expensive and complicated to use. The dog's heart rate

is an extremely sensitive indicator of autonomic tone, often shifting dramatically in response to sympathetic arousal and showing varying degrees of receptiveness to countervailing parasympathetic influences indicative of autonomic balance. Suggestive autonomic information providing a rough index of sympathovagal tone may be derived by tracking cardiac recovery patterns in response to startling or provocative events and the modulation afforded by the delivery of arousing and calming stimuli. In addition to monitoring the dog's autonomic changes in response to petting and other rewards, various changes associated with orienting and attending, leash prompts and saccades, training modules and routines (e.g., sit-stay and down-stay training), and relaxation effects mediated by PFR can be monitored and tracked over time.

The author has found that a variety of inexpensive and readily available heart monitors can be useful for tracking autonomic shifts during training and the behavior-therapy process (see Vincent and Leahy, 1997; Stichnoth, 2002; King et al., 2003). Sports monitors provide a useful real-time window for observing and quantifying a dog's response to various training and counterconditioning procedures. These relatively inexpensive radiotelemetry devices can be attached to a harness to prevent the elastic band from shifting off the heartbeat signal. The effective use of such devices through dog hair requires that an electrode gel be applied on the skin to establish a viable signal. The monitor is attached to the top of the harness, making easy viewing possible. In addition to sports heart monitors that are fitted around the chest of a dog for recording real-time heart-rate changes, wrist-type heart-rate and blood-pressure monitors are available. Reasonably priced cuff-type monitors together with recording and graphing capability are also available and useful, especially for tracking changes in the relaxation response during PFR training. Various tympanic thermometers are readily available for measuring changes in temperature, including one device designed for dogs. Pill-sized telemetry devices are also available for tracking temperature. These pill thermometers are designed to be ingested and to transmit core temperature data. Pill thermometers offer a nonintrusive way to monitor and record real-time temperature changes (O'Brien et al., 1998), perhaps having unique applications for following stress-related changes associated with canine behavior problems. Real-time temperature information might be particularly revealing, perhaps providing a biological marker useful for the diagnosis as well as tracking the outcome of treatment efforts. Given the apparent close relationship between emotional regulation and thermoregulation, sympathovagal disturbances affecting a dog's ability to regulate fear and anger may be expressed in the form of temperature changes. In addition to temperature, other pill-sized sensors might be developed to measure stomach acid content (a stress measure) and other relevant biochemical changes affecting the gut in association with stress. Movement and general activity levels can be tracked and quantified by pedometers.

However, what is really needed is the ability to monitor simultaneously the activity of several relevant physiological parameters to establish a signature profile or configuration of specific physiological arousal states that are unique correlates of the target problem behavior. In addition to heart rate, devices measuring activity levels, respiration rates, skin potential, changes in muscle tone, and temperature, perhaps incorporated into a collar worn by the dog and receiving signals directly from the neck and from a vest containing ambulatory monitoring equipment, might be designed to track prominent autonomic changes in anticipation of aggression. In the case of dogs that give little or no advanced warning before reaching a flash point of no return, such devices might help to identify specific markers that regularly precede aggressive episodes and help to facilitate behavior-therapy efforts. Canine biofeedback collars might be programmed to automatically deliver various sensory stimuli to interrupt the aggressive sequence at an early and flexible stage or to provide the trainer with radio-controlled means to activate stimulation, perhaps involving attention-stimulating auditory stimuli, the delivery of odors that can increase parasympathetic tone at the critical moment,

and various other stimuli able to interrupt the aggression sequence and to induce behavioral inhibition. Electronic training collars incorporating biofeedback capabilities might be useful in the treatment of numerous behavior problems.

AUTOSHAPING AND AUTOMATED TRAINING

The full-body restraint and passive-exposure apparatus and techniques described by Williams and colleagues (2003) require little involvement of the owner or behavior therapist. The dog is simply put in a box, covered completely in a material that prevents movement and slowly exposed to the approach of a target or person. It is easy to imagine how such a technique might be further automated. Electronic products of various kinds are reportedly being developed with the goal of getting dogs to train themselves. Dunbar (2000) has dubbed the methodology *autoshaping*, borrowing the term from an experimental procedure in which laboratory animals are trained to manipulate levers and switches to obtain food reinforcement without the experimenter's aid. Dunbar predicts that autoshaping will revolutionize the way dogs are trained: "Electronics can train a dog by a flick of a switch overnight. The autoshaping revolution will be mind boggling" (transcribed). In addition to electronic collars emitting low-level electrical pulses, devices that Dunbar calls *tickling collars* and other electronic control devices designed to distract dogs in various ways will be programmed to interrupt and shape behavior automatically, presumably with the aid of a programmable food-delivery mechanism. Although autoshaping procedures and environmental programming may eventually offer significant applications for the control and management of certain behavior problems, in principle such procedures and goals are problematic with respect to the objectives of cynopraxic training and therapy. Certainly, owners lacking sufficient time or incentive to train their own dogs will be attracted by quick-fix devices offering effortless overnight gratification; however, nothing can ultimately take the place of the interactive and shared experience of training. Ironically, even designers of robotic pets have recognized the importance of interactive training to make entertainment robots seem more natural, gratifying, and pleasant (Kaplan et al., 2002):

> One of the challenges and pleasures in keeping a real pet, like a dog, is that the owner has to train it. A dog owner is proud when he has the impression that his pet changes its own behavior according to his teaching. We believe this is also a way for an interesting relationship to emerge between an entertainment robot and its owner.… This paper focuses on a method for teaching actions to an animal-like entertainment robot. Of course, the simplest way would be to allow the owner to program directly new actions for the robot. But for the purpose of entertainment robotics it would be much more interesting if this teaching would take place only through interactions, as it does with real pets. (197)

According to the authors, programming robotic dogs to behave in predetermined ways, without giving the user the ability to change a robot's behavior through training, significantly diminishes the potential fun and gratification derived from interacting with such pet toys. If automatic control is not satisfying for the users of robotic toys, how much less gratifying would autoshaping techniques be for the owners of sentient dog companions. By excluding the owner from the training process, autoshaping risks causing the dog to become progressively mechanized and detached from the owner as a source of predictability and control. Instead of enhancing the bond and the dog's quality of life, such products and techniques may serve only to reduce and constrict the human-dog bond while further alienating the dog from the home and family. Indeed, as a dog becomes an automated household accessory, one may gradually need devices to record and evaluate the dog's progress and emotional state. One such device, called a *Bowlingual* (Takara Corporation), may already be here (Tham, 2002). If it lives up to its maker's claims, the device would nicely fit into the futuristic autoshaping scheme. The collar device is equipped with a wireless microphone to pick up and

transmit vocalizations to a receiver that interprets the bark, howl, whine, yelp, and so forth into a literal translation of how the dog feels and projects it on a small terminal screen (e.g., "I'm sad"). In addition, the device can record vocalizations when the owner is not at home, providing a summary of the dog's emotional state and mood during the day.

Numerous electronic devices are currently available for monitoring and interfacing with dog behavior via various means of radio- and behavior-activated stimulation. Inexpensive noise-activated recorders and movement-sensitive video cameras provide extremely useful baseline and treatment-tracking information. Many of these devices have been previously discussed in the context of controlling destructive behavior (see Chapter 2). The most frequently used deterrent interface typically involves noise stimulation via booby traps and alarms activated by infrared or movement/vibration detectors. Such devices can be highly effective for controlling many nuisance problems, but the suppressive effect of loud noise for many dogs is problematic, especially with respect to the control of highly motivated behavior. Although initial exposure to a loud noise stimulus evokes pronounced startle, repeated exposure typically results in gradual habituation and loss of aversion. Further, dogs possessing high-startle thresholds may require noise stimulation at a level of intensity that potentially risks doing physiological harm to the ear (e.g., a nautical horn) (see Campbell and Bloom, 1965).

PART 2: ELECTRONIC TRAINING

Note: Throughout the following discussion, the terms used to describe electronic training collars (e-collars) and electrical stimulation (ES) are self-explanatory or specifically defined, as needed. However, one terminological decision requires some explanation to head off potential confusion. Specifically, the term *electrical stimulus* or *e-stimulus* has been selected to replace the word *shock*. The term *e-signal* is used in cases where a dog has learned to respond to the e-stimulus as an avoidance cue. There are several reasons for this decision. First, at low levels, the term shock is hardly fitting to describe the effects produced by electronic training collars, since there is virtually no effect beyond a pulsing tingling or tickling sensation on the surface of the skin. Second, the word shock is loaded with biased connotations, images of convulsive spasms and burns, and implications associated with extreme physical pain, emotional trauma, physiological collapse, and laboratory abuses. Third, the e-stimulus or signal generated by most modern devices is highly controlled and presented to produce a specific set of behavioral and motivational responses to it. In general, the terms e-stimulus, e-signal, and ES have been decided on for the sake of neutrality and because they more accurately describe the low to medium electrical events produced by radio-controlled and behavior-activated e-collars. In most cases where historical research has referred to ES as shock, the original terminological convention is maintained.

Currently, the most common aversive interface and deterrent used in dog training is ES. The use of electronic training devices is the subject of significant controversy and the propagation of misinformation and exaggeration on both sides of the debate. Historically, dog trainers working with hunting dogs were the primary end users of commercial electronic training collars. These early collars reputedly generated a harsh shock, causing significant pain and distress to dogs. In addition to producing a highly aversive shock, these early devices were prone to significant reliability problems, such as discharging in response to extraneous radio signals. In contrast, the safety and reliability of most modern electronic training and behavior-control devices have been significantly improved. Most current devices deliver a highly controlled e-stimulus, ranging from low levels of stimulation (imperceptible or just barely perceptible to human touch) to higher levels capable of causing significant startle and discomfort. High-quality contemporary devices enable trainers to select stimulation levels that precisely match a dog's needs, tolerance for ES, and training objectives, thereby prevent-

ing excessively painful stimulation and unnecessary distress.

The combined advantages of immediate and reliable radio-controlled delivery of precisely regulated ES make electronic training a viable and humane alternative to many traditional techniques for applying negative reinforcement and punishment. Traditional techniques can be effective when skillfully used, but they are often encumbered by undesirable side effects associated with interactive punishment, poorly regulated force, and retroactive timing. Finally, although potentially capable of producing significant psychological distress and harm when used improperly, electronic training devices are relatively safe and humane when used competently and selectively. Recently, the Delta Society, in cooperation with dozens of nationally recognized dog-behavior and welfare experts, has produced a document outlining professional humane standards for the dog-training profession. Both radio-controlled and behavior-activated electronic devices have been recognized as effective and humane training equipment when used properly and in accordance with humane principles (Delta Society, 2001). Given the potential benefits of radio-controlled electronic training and the relatively safe nature of ES, professional dog trainers are well advised to master the basic technical knowledge and behavioral skills needed to use such tools effectively and humanely.

Today, a variety of products are available over the counter for purchase and use by ordinary dog owners possessing little behavioral knowledge or understanding of the benefits or potential harm that can result from the improper use of electronic training equipment. Obviously, for proper and humane use, electronic training devices require support instruction and knowledge of basic-training principles; nonetheless, large numbers of radio-controlled e-collars are sold in pet stores to relatively naive and inexperienced dog owners without much in the way of appropriate instruction regarding their use, misuse, and potential for abuse. Unfortunately, the instructional material typically packaged with these powerful training tools is woefully inadequate. This neglect poses a significant welfare concern that should be addressed by responsible manufacturers and distributors of these products. Without proper instruction and guidance, electronic training collars cannot be used competently and humanely, and, in the hands of misinformed or incompetent users, e-collars can all too easily become instruments of abuse and cruelty. Of course, a similar criticism can be made concerning many other training collars and tools commonly used in dog training. Nevertheless, the radio-controlled and push-button operation of electronic devices poses special problems that justify additional concern with respect to misuse and potential for abuse. Furthermore, with promises of rapid control and instant gratification, impatient and unknowledgeable dog owners may resort to electronic training as a push-button panacea, without first giving conventional reward-based training methods a chance to succeed. Lastly, since there is considerable variation in the ES produced by e-collars, manufacturers should freely disclose critical information concerning the output of their collars, including open-circuit voltage, closed-circuit voltage, current and power, and pulse and waveform characteristics (pulse duration and pulse repetition rates), together with explanations regarding the significance of such specification in order to help consumers and professionals select devices best suited to their needs. Sadly, most of the manufacturers that the author contacted for information concerning output specifications either did not reply or were strangely evasive and uncooperative, arguing that such data were of a proprietary nature. Of course, all the needed electrical output and waveform information needed can be obtained with an oscilloscope. Further, reasonably accurate output comparisons can be obtained with a true RMS multimeter. Many of the details regarding circuit design and output specifics can also be obtained by consulting patent claims.

Although low-level electrical stimulation (LLES) is humane and highly effective, electronic training devices should not be used in the absence of reward-based training, nor should they become a crutch or a way of life. Success in electronic training is achieved when it is completely replaced by reward-

based training efforts. As a humane process, cynopraxic training strives to enhance affection, mutual appreciation, and trust between people and dogs, steering the relationship toward the ideals of interspecies cooperation and interactive harmony. Training is a lifelong process of befriending the dog—a process of mutual understanding and care that is most fully and satisfyingly achieved through gentle and considerate means. Excessive reliance on aversive procedures for controlling a dog undermines the attainment of these goals and risks damaging the relationship. Ultimately, the value of electronic training is measured by its ability to limit or extinguish itself, while at the same time liberating the dog from unacceptable behavior impeding a more enriched and rewarding life experience with people. Unfortunately, just as electronic training offers many significant benefits, it is fraught with significant risks of abuse and misuse. Instead of being used as a humane tool for enhancing the human-dog bond and improving a dog's quality of life, electrical control may be abused to enslave a dog by means of fear and pain. Using electrical control procedures to dominate a dog for the sheer sake of domination and exploitation is offensive and violates human sensibilities and the goals of cynopraxic training. Of course, similar concerns and considerations should guide the use of all aversive techniques used in dog training and behavior therapy.

Technical Considerations

Electrical Potential, Current, and Power

The relative potential of ES to produce pain or distress depends on a number of variables that are often ignored or underappreciated. Putting aside individual differences and psychological factors (e.g., the predictability and controllability of the event), parameters such intensity, frequency of application, duration, and location of ES figure prominently into the sort of experience that bioelectrical stimulation produces (Price and Tursky, 1975; Sang et al., 2003). The e-stimulus is focused on a circumscribed area of skin tissue located immediately beneath and between the electrodes, referred to as the *electrode-skin interface*. Because e-collars are designed to limit arcing, both electrodes of the stimulator need to make close contact with the skin to establish a closed circuit. Separation of electrodes from a dog's skin by thick hair or air of a distance greater than 1 millimeter will result in an open circuit. The high-voltage arcing of modern e-collars is minimal and may require magnification and darkened surroundings to view.

When discussing the effects of ES, some care should be exercised not to confuse electrical categories or phenomena. A common error is to equate voltage with current. Electrical potential or *voltage* is relative and depends on the electromotive difference between two points, whereas *current* refers to the amount of electrical charge or amperes flowing between those points over some period. The electrical quantity of a current is measured in coulombs (C), whereby 1 ampere (A) equals a flow of 1 C per second. A Van de Graff generator produces in excess of 300,000 volts (V) of electrical potential (the equivalent of a stun gun) but is relatively harmless to touch. On the other hand, as little as 25 V can be lethal to a person. The critical factor is the amount of energy (joules) or power that flows through the body. When one scuffs along on a carpet, the body accumulates a charge of several thousand volts, and voltage levels may rise to 3000 V or more when getting out of a car. Nevertheless, the energy released is miniscule, something on the order of 0.005 joules (J). The output of an e-collar tested by the New Zealand Department of Scientific and Industrial Research (Dix, 1991) was found to produce 3000 times less electrical energy than that allowed by standards for electrical fences, six times less electrical energy than that produced by the static discharge produced by walking on a carpet, and 50 times less than what is considered necessary to reach pain thresholds. Although the collar was estimated to produce a peak open-circuit amplitude of 961 V, when a current was passed through a 500-ohm load (simulating the electrode-skin circuit), a peak voltage of 58 V was found to drive a current of 116 milliamperes (mA) for 0.78 milliseconds (msec). When converted into energy values, the foregoing output current at peak amplitude and

duration was determined to be on the order of 1.2 millijoules (mJ). Kouwenhoven and Milnor (1958) demonstrated that extremely brief low-energy (0.0001 to 2.4 J) high-voltage shocks of 40,000 V in anesthetized dogs could not induce ventricular fibrillation, cardiac arrest, or "any other untoward effect" (45).

The following analogy may help to clarify some important distinctions between voltage, current, and resistance. Imagine a scenario involving subway train and two conductors. The first conductor forces passengers (electrons) into a train car while his twin pulls them off again as quickly as they board. The force that the first conductor uses to push the passengers on board will depend on the size of the entryway and any obstructions blocking the flow of passengers within the train itself. Similarly, the force used to pull the out passengers again will depend on internal resistance and the size of the exit (out-circuit impedance). To the extent that both conductors push and pull the passengers (electrons) in and out of the train, a current or flow of charge is established between them, without either of the conductors actually entering the train themselves. As such, voltage can be described as the pressure or force needed to cause a current of electrons to flow between two points of a closed circuit; *voltage* always implies difference and distance, whereas *current* implies movement and time. A current of electricity is conducted through the electrode-skin circuit at a certain rate or amperage depending on the combined resistance and capacitance (impedance) of the conducting circuit. The various relationships between voltage (E), resistance (R), and amperage (I) are derivable from Ohm's law: $E = IR$. For example, provided that one knows the amperage and resistance of a circuit, one can then calculate the voltage by multiplying the values together. For example, a 20-mA current requires 14 V of electromotive force to move through a circuit having a 700-ohm resistance. Similarly, by dividing the known voltage by the circuit resistance or load ($I = E/R$), the amperage can be obtained. The amount of electrical energy used by a circuit as a current passes through it is described in terms of temporal and heat units (e.g., amperes, watts, and joules).

When authors make statements about radio-controlled stimulators delivering shocks at a level of 3000 V, the reader may picture an event quite different than what actually occurs. The practice is doubly problematic when open-circuit and closed-circuit categories and measures are mixed together. The voltage between two electrodes of an open circuit may equal several thousand volts, and e-collars may generate open-circuit voltages of 3000 to 10,000 V, but one cannot sense the open-circuit voltage even though an electrical field radiates between the two electrodes of an activated e-collar. The open-circuit voltage is expressed as the difference in charge, electrical potential, or electromotive force between the electrodes. Without knowing other variables, however, such as the total impedance of the electrode-skin circuit, the amperage of the current, and the duration of the electrical event, the open-circuit voltage of the collar is not very meaningful information with respect to estimating the intensity of the e-stimulus reaching a dog. Referencing the open-circuit voltage may lead to unjustified connotations of severity. Christiansen and colleagues (2001a), for example, have claimed that the e-collar they used to suppress predatory behavior delivered an astounding 3000-V shock at 0.4 A. The notion that electronic training collars generate a 3000-V shock at 400 mA is misleading and must be wrong, since doing so for a 1-second period, as reported, would generate an astounding 1200 J of electrical energy—enough energy to light twelve 100-watt (W) light bulbs for 1 second. The authors appear to confuse the electrical potential between electrodes of an open circuit with the voltage between electrodes establishing a closed circuit—only a closed circuit can produce a flow of current capable of producing electrical power. With the current density localized around the small-diameter steel electrodes, such levels of shock as described by Christiansen and colleagues would likely seriously damage the skin. Finally, even though a particular e-collar may generates an open-circuit electrical potential of 3000 V, the actual operational voltage driving current through

the electrode-skin circuit is far less. According to Ohm's law, an e-collar set to produce a current of 12.8 mA through a 100-ohm load would require a voltage of 1.28 V. The same current flowing through a 1000-ohm load requires 12.8 V. These predictions obtained from Ohm's law are closely reflected in actual measurements obtained with a true RMS digital multimeter (Extech 22-811). The voltage output or amplitude of a popular e-collar driving the aforementioned current value (12.8 mA) through 100-ohm and 1000-ohm loads was measured at 1.27 V and 10.3 V, respectively.

To avoid some of the confusion that occurs when the output specifications of collar devices are reported in the scientific literature, it would make sense to report such information in terms of closed-circuit values based on some load constant (e.g., 700 ohms) or in terms of a power-output formula (Forbes and Bernstein, 1935). Power or watts is the rate of energy dissipated over some period. In a closed circuit, the amount of electrical energy produced is based on volts, current, and time (t): energy = t(EI), and 1 W is equal to the use of 1 J of energy per second. Consequently, power (P) is derived from the collar's voltage (E) times its amperage (I), or P = EI, making it a potentially useful value with respect to estimating the stimulation effect of an e-collar's output. In addition to quantitative parameters (e.g., current density and power), the subjective sensation produced by the e-stimulus is strongly affected by its waveform. The pulse duration and pulse repetition rate (frequency) are major determinants of the relative aversiveness or intensity of a current at a given amplitude flowing through the electrode-skin circuit. Keeping current and impedance constant, the subjective effect of the e-stimulus can be strongly affected by changes made to the pulse duration and pulse repetition rate (frequency), with longer pulse durations and increasing repetition rates producing more aversive effects (Kaczmarek et al., 1991). Many e-collars appear to shift intensity levels by altering the pulse duration or repetition rate while keeping the output current and voltage relatively constant, depending on the electrode-skin load. In such devices, the pulse amplitude (voltage) is less important with respect to the actual intensity of the e-stimulus produced. Although an oscilloscope is needed to graphically display the various changes in pulse amplitude, duration, and repetition rates, a multimeter can be used to get a general idea of the relative pulse duration at different levels of intensity via frequency and duty-cycle readings. The *duty cycle* represents the ratio of the pulse duration to the pulse period expressed as a percentage.

Electrode-Skin Interface: Resistance and Capacitance Factors

The combined resistance and capacitance of the electrode-skin circuit is referred to as its *impedance*. The impedance determines the amount of voltage needed to cause a current of electrical charge to flow through it; the higher the impedance is, the more voltage is needed to establish a flow of current. The voltage output of many e-collars appears to shift up or down in response to changes in fur and skin resistance, with an upper output limit set to prevent excessive discharge and heat-generative arcing. In addition, a current limiter is built into these devices to reduce the risk of malfunction and delivery of dangerous shock. These bioelectrical design features enable the device to compensate safely for individual impedance, thereby ensuring that a highly discrete and measured dose of ES is delivered, depending on the individual characteristics and needs of a particular dog. Brief doses (momentary), as commonly used to support avoidance training, typically require higher-amplitude stimulation to reach threshold values, whereas longer-duration (continuous) doses of ES appear to establish a circuit at a lower amplitude via ionic microenvironment changes localized around the electrodes, vascular dilation (Greenblatt and Tursky, 1969), and other changes conducive to reduced impedance (Sang et al., 2003). Continuous stimulation techniques enable a trainer to apply LLES effectively at levels that do not exceed the threshold values of A-beta sensory pathways (tickle and tingle effects).

The condition of a dog's coat and the outer layers of the skin (stratum corneum) are

the primary sources of cutaneous impedance. An important impedance factor is the skin's level of hydration, with dry and oily skin requiring more voltage than moist skin. Although skin moisture may improve its conductivity and increase the flow of current between electrodes (Chesney, 1995), external wetness may actually shunt current away from the electrode-skin interface and decrease current flow. Insulating the exposed sides of the electrodes with rubberizing paint may help to reduce current diversion due to wetness. Skin resistance varies between 10,000 to 100,000 ohms (or more depending on location) for dry skin and 1,000 ohms for skin that is well hydrated (Klein, 2000). The e-collar used by Tortora (1983) was reported to produce a pulse train having a 255-Hz repetition rate (50% duty cycle) with a peak voltage, measured across a 100,000-ohm load, estimated to be 1134 V. The high voltage of e-collars is designed to jump small gaps (1 millimeter) and pierce resistance barriers caused by bits of fur lying between the electrodes and the skin. Electrical arcing occurs when the electrode loses contact with the skin and the circuit is slightly opened. Relatively high voltage is needed to generate an arc between the electrode and a dog's skin. After the cutaneous resistance is transited by a brief high-magnitude pulse, skin impedance drops to a mean of 700 ohms (Kouwenhoven and Milnor, 1958). Measurements taken between internal and external electrodes have determined that the out-circuit impedance for dogs ranges from between 100 and 5000 ohms (Niwano et al., 2001). Subcutaneous resistance was measured to range between 95 and 225 ohms, whereas skin impedance at 10-V pacing showed significant variability, ranging from 460 to 16,600 ohms, depending on the size of the electrode used.

The impedance of the electrode-skin interface is also strongly influenced by the electrode diameter (Kaczmarek et al., 1991). Narrow-diameter electrodes require significantly more electrical potential to generate a charge that will pass through the skin (Forbes and Bernstein, 1935). In addition, since the current density concentrates at the out edge of the electrode, narrow-diameter electrodes, as used in e-collars, produce a highly localized and focused effect. The disadvantage of high-voltage ES is that the current density is established immediately beneath the electrode, which is prone to produce a pricking effect at levels just above detection thresholds (Kaczmarek et al., 1991; Poletto and Van Doren, 1999), perhaps in association with microscopic arcing around the outer rounded edge of the electrode, requiring great care to avoid eliciting pain when increasing stimulation amplitudes. In contrast, larger electrodes, as used in transcutaneous and neuromuscular electrostimulators, produce stronger ES intensity levels at lower pulse amplitudes and current levels.

The impedance load of the electrode-skin interface decreases as current increases, requiring less voltage at higher amperage levels, a principle applied to the design of transcutaneous electrostimulators. The cutaneous load also appears to be affected by the frequency of the pulse train (Rosell et al., 1988), with high-frequency pulses passing through the skin-impedance barrier more freely than low-frequency pulses. As pulse duration and pulse repetition rate are increased, the subjective magnitude of the e-stimulus is intensified. A major advantage of constant current devices is that they can shift the level of ES by altering the pulse duration or repetition rate rather than relying on changes to the pulse amplitude, thereby reducing the risk of discomfort generated by increased voltage in association with narrow-diameter electrodes. Many modern e-collars appear to hold pulse amplitude (voltage) relatively constant, altering output intensity by changing the pulse duration and repetition rates of the e-stimulus. Other devices alter output intensity by increasing pulse amplitude and keeping pulse duration and frequency relatively constant, depending on the electrode-skin load. When skin resistance is low, pulse amplitude is decreased; whereas when skin resistance is high, pulse amplitude is increased. The high, medium, and low variations that are generated at different levels by some collars appear to be achieved by altering pulse duration and repetition rates rather than involving changes affecting output amplitude.

Threshold Values

Prior exposure to ES exerts a number of modulatory influences over electrocutaneous thresholds, with experienced human subjects tolerating at least twice the electrical intensity tolerated by naive subjects (Kaczmarek et al., 1991). Although long-duration ES results in a reduction in cutaneous impedance, it is also associated with stimulus fatigue and a reduced sensitivity to the e-stimulus (Tursky et al., 1970). Consequently, low-level continuous stimulation used in the context of attention training may help to elevate reactive thresholds, thereby reducing the risk that medium-level ES will evoke adverse arousal. The presentation of brief nonpainful prepulses of ES also serves to elevate pain thresholds. Studies with human subjects have shown that presenting a 0.5-second prepulse of ES 40 to 60 msec before a stronger ES serves to reduce pain thresholds significantly (Blumenthal et al., 2001). In persons with low-pain thresholds, 40-msec prepulses of current set to match perceptual threshold levels resulted in a 54% reduction in perceived pain. Presenting a vibratory stimulus to dogs just in advance of the electrical event (60 to 300 msec) appears to help reduce startle arousal while at the same time facilitating the integration of the event as an informative signal via sensorimotor gating processes. Another useful technique for reducing the risk of reactive responses in dogs with low thresholds is to introduce ES gradually in combination with a continuous vibratory stimulus overlapping the e-stimulus.

Surprisingly little data have been reported about dogs with respect to electrical threshold values. What little is known suggests that the thresholds for shock produced by high-voltage generators (approximately 500 to 600 V at 60 Hz) do not significantly differ between puppies and adult dogs (Lessac and Solomon, 1969). The minimum electrical intensity required to evoke a leg flexion for both puppies and dogs was found to be around 0.80 mA (range, 0.50 to 1.25 mA). The yelp response in both young and adult dogs was evoked at approximately 2.80 mA (range, 2.0 to 3.0 mA). Brush (1957) found that the efficiency of avoidance learning increases with intensities up to 4.8 mA, with latencies to escape appearing to increase at intensity levels above 5.0 mA. The maximum electrical shock delivered to the feet without inducing tetany has been determined to be around 10.0 to 12.5 mA (Solomon and Wynne, 1953). These specifications are not of much relevance with respect to e-collars, however, since significantly more electrical amplitude is needed to reach the detection threshold in the case of narrow-diameter electrode devices than is required by the larger electrodes and grids used in the experimental setting. At 500 V, a sustained current of 6.0 to 8.0 mA passed through a narrow electrode, as used in e-collars, barely reaches detection thresholds; however, the same current applied through a 2-inch-diameter electrode produces extreme discomfort. Conversely, directing the lowest detectable current produced by an e-collar through a 2-inch electrode results in a highly aversive event.

Standardization and Safety Considerations

Although many advances in collar design and quality have been made over the past several years, there is a significant lack of product standardization. The quality of electronic training collars varies among manufacturers, but most provide the means to adjust the collar to deliver stimulation at low and medium levels, producing a tickling or tingling effect, as well as high level electrical stimulation (HLES) capable of producing significant pain and distress in most dogs. High-quality collars produce a smooth stimulus effect, whereas cheap and poorly designed devices tend to produce a rough and unpleasant sensation, even at low levels, making them inappropriate for cynopraxic training purposes. Unfortunately, many devices produce a high-end shock that *far* exceeds what is needed by the average dog and owner. Although an occasional dog may need the higher levels of stimulation, such devices should be made available only through special order. Alternatively, an electronic key or code might be inserted into the circuit of such devices that would keep the high-end off, at least until the user found a real need for it and requested the code from the manufacturer. Such owners could be given

appropriate counseling and referrals to trainers for further advice and instruction on how and when to use HLES. The ability to switch from low, medium, and high scales would provide the user with a greater range of output levels to meet specific needs and reduce the risk of accidental painful shock.

The high-end output of certain contemporary devices suggests the need for an optional safety device to prevent ES from occurring above a certain level and to prevent activation by unauthorized users (e.g., children). Accidental stimulation at high levels can produce significant distress and emotional harm to a dog. There is also a need for a product that would enable trainers to shape the e-stimulus according to specific needs. Devices that would enable professional users to set pulse amplitude, durations, and frequency (waveforms) as well as to control the duration of momentary stimulation and pulse-burst patterns would be highly desirable in the context of behavior-therapy applications. An external electrode interface might be designed to capture and condition collar output in various ways to make it safer and more compatible with low-level electrical training procedures. Meanwhile, the effective electrical output of an e-collar can be easily stepped down by placing an appropriate voltage divider (resistor) or miniature potentiometer between the electrodes. The lower the resistance is, the more voltage is shunted away from the skin. By carefully selecting a resistor with the correct ohm value, the entire output range of the collar can be adjusted down to low levels of ES, converting the strongest e-collar into a "tickle collar." The resistor wires should be appropriately sealed with nonconducting paint or sheathing. (*Note:* Users should check with the manufacturer for specific instructions and safety guidelines pertinent to such product modifications.)

Subjective Factors and Electrical Stimulation

Electricity is a basic force of nature and life itself, with electrical currents streaming along the double-helical strands of DNA (Boon and Barton, 2002) and mediating every sensory transmission and action of the body. Nerve cells communicate with one another through the exchange of minute electrical charges, thereby producing sensory feelings of pleasure and pain and all forms of neural activity and bodily movement from the most primitive reflex to complex thought processes and motor skills. Millions upon millions of electrical signals travel through the body unnoticed while serving critical biological and behavioral functions. Given the ubiquity of electricity, it seems odd that dogs and most other mammals have not evolved sensory receptors specifically dedicated to sensing electrical stimuli.

While a true RMS multimeter or an oscilloscope can give trainers useful technical information, the direct experience of the e-stimulus translates the quantitative specifications into a qualitative and subjective appreciation for the event. Knowing the electrical dynamics of the e-stimulus is helpful for many reasons, but nothing can replace the feel or subjective index of stimulus quality and magnitude—the most sensitive way to evaluate the e-stimulus is to feel it. The subjective experience of electricity arises from the activation of cutaneous mechanoceptors. When touch receptors are activated by noxious stimulation or injury, electrical impulses communicate to the brain that damage or a threat of physical injury has occurred. Although the e-stimulus used in dog training does not produce any physical damage to the skin or underlying tissue, its presentation produces an illusion of noxious stimulation by activating mechanoceptors transmitting tactile sensations along myelinated A-delta and A-beta fibers (Sang et al., 2003). At low-intensity levels, low-threshold myelinated A-delta fibers transmit tapping, tickling, tingling, twitching sensations, whereas, at medium levels, high-threshold A-beta fibers are triggered evoking sharp pricking and jabbing sensations. Higher levels of ES may activate high-threshold cutaneous and muscular C-fiber nociceptors and mechanoceptors associated with a burning sensation. The throbbing and burning aftersensations of painful trauma are transmitted by high-threshold unmyelinated C-fibers occurring as the result of physical

injury. Although no actual injury occurs, the reflexive actions elicited by aversive ES and the instrumental behavior emitted by dogs at such times are similar in many respects to responses occurring when physical pain is actually experienced (e.g., inhibitory startle and escape).

The advantage of ES is that it can be presented in highly controlled (intensity, duration, and density) and timely doses, producing corresponding levels of behavioral arousal, ranging from increased alertness and searching activity to intense startle and frantic escape efforts. Essentially, ES appears to confuse local mechanoceptors and nociceptors, causing the organism to respond as though a significant contact threat was present requiring immediate attention and escape. The e-stimulus is a purely subjective and psychological event. Tortora (1982) nicely states the aversive illusion produced by LLES:

> Safe electrical stimulation utilizes your dog's senses and causes your dog to respond as if there is physical damage, when in reality no damage is occurring. There is no better way to cause safe, timely, controllable short-term discomfort. (11)

Radio-controlled electronic training techniques can be divided into three general categories, depending on the behavioral objective and level of stimulation:

Low-level ES (LLES): escape/avoidance (negative reinforcement) and safety training
Medium-level ES (MLES): inhibitory training (punishment and negative reinforcement)
High-level ES (HLES): rapid suppression and aversive counterconditioning.

At low levels, the e-stimulus is annoying and disruptive; at medium levels, it is startling and inhibitory; and, at high levels, it can evoke significant pain and emotional distress. Although collar-produced shock can produce acute pain, the painful event does not and cannot produce physical injury. Pain is the subjective experience associated with somatic irritations and traumatic injury (e.g., stinging, throbbing, aching, or burning sensations). The experience of electrical pain is highly variable and not dependent on the activation of nociceptors specific to electricity; in fact, the mammalian somatosensory system appears to lack receptors specifically dedicated to electrical stimuli. Significant individual differences exist with respect to the dog's tolerance for electrical pain. In addition to the dog's temperament and relative threshold sensitivities to aversive stimulation, the subjective experience of pain is modulated by a number of variables, including stress, fear, frustration, and anger. Further, pain thresholds can be significantly elevated by the elicitation of incompatible emotional and motivational states associated with olfaction, food, sex, massage, affection, and the effect of person. On a neurophysiological level, the pain associated with strong ES is modulated to some extent by the secretion of opioid substances in the brainstem that interact with nociceptive signals (Johnson, 1998).

Although electronic training devices can produce significant pain and distress, the subjective effects of low to medium ES do not warrant the term *pain*, as defined by the International Association for the Study of Pain (IASP) (Merskey and Bogduk, 1994). The IASP defines pain as "An unpleasant sensory and emotional experience associated with actual or potential tissue damage, or described in terms of such damage" (210). The standard set by the IASP clearly makes a distinction between stimuli producing momentary discomfort, but which are physiologically harmless, and states of pain resulting from actions leading to or having the capacity to produce injury: "Experiences which resemble pain but are not unpleasant, e.g., pricking, should not be called pain" (IASP, 2003). These distinctions appear to exclude the low-level to medium-level e-stimuli that produce a pricking sensation from being referred to as pain. As such, pain is subjective and depends on the evocation of an emotional state evidencing significant discomfort and distress.

Further, the physiologically harmless ES produced by e-collars should not be lumped with ordinary household electrical shock because the former has no potential for injuring tissue whereas the latter can produce physical injury, including severe burns. As such, the e-stimulus is not a priori a painful

event and can be applied to the skin without producing any pain whatsoever. The most interesting and useful applications of the e-collar involve stimulation levels at just above threshold levels—tickles, tingles, and twitches. Electrical stimulation producing pricking sensations is also used without generating significant pain or distress. In fact, the vast majority of training objectives using ES involve low and medium levels. HLES is reserved for aversive counterconditioning, often delivered in the form of extremely brief momentary pulses and used for such things as snake proofing and the suppression of predatory behavior.

Though dogs may find ES alarming at low levels and startling at medium-intensity levels, these stimulation levels are far less aversive or intrusive than many conventional corrections delivered by slip, prong, or halter collars. Even when ES is delivered at moderately high levels, the subjective sensation of momentary stimulation approximates the feeling of a standard-sized rubber band stretched 5 or 6 inches away from the skin and released sharply on the wrist. Repeated ES delivered to the human hand at various levels used for training purposes produces no redness and minimal lingering sensations of discomfort. Comparable stimulation with a rubber band results in significant irritation and redness, and aching persists. Traditional training collars and tools produce an aversive effect by various means, such as abruptly compressing or jabbing the neck (slip and prong collars), clamping around the muzzle and twisting the head and neck (halter collars), or sharply striking the dog's body (e.g., throw objects). All of these techniques are relatively safe and humane when used properly but could damage the throat or neck if misused or abused. Electronic stimulation, on the other hand, is distinguished by being relatively harmless with respect to producing physical damage to a dog's skin or body. Furthermore, since mechanical techniques work by forcefully stimulating mechanoceptors and nociceptors, such tools may cause local irritation or muscle strain. Unlike the aversive effect of ES, which rapidly dissipates after being discontinued, forceful stimulation of skin and muscle tissue can result in a chain of biochemical events that may cause sustained throbbing, local irritation, or bruising.

Anyone who has ever witnessed a dog experiencing acute (real) pain knows that they yelp repeatedly and show other autonomic and behavioral signs of sustained and unmistakable agony. The response dogs typically show in response to low to medium ES cannot be construed as pain. Dunbar (2000), during a panel discussion on dog-training equipment at the Tuft's Expo, acknowledged the capacity of "electronic stimulation collars" to produce a harmless and effective stimulus for training dogs, suggesting that such devices offer unique alternative for humane punishment:

> When you see an electronic stimulation collar working, then we need a different word for it, it's a "tickling collar" is what it is. And, you know, go to the companies; ask them, "Do you have anything that tickles me?" Put it on your hand, zap it out; so, I guarantee that we will have dog-friendly e-collars and autoshaping devices that do loads. They will be distracting dogs in all sorts of ways: with wisps of smells, uh, sounds that we can't hear, and maybe little tickles on the skin, and what have you. Then I think that the dog training area will start to come together, because you now have a greater choice of the punishments that you can choose on. And now, there is literally no need ever, ever to shock a dog. There, there's no need for it. No one can convince me of that. Why? Because we have the alternative, it's high tech, yeah, but it doesn't hurt. (transcribed from audio recording)

Just as dropping a bowling ball on one's foot will certainly produce a significantly different effect than that produced by a falling tennis ball, ES produces variable subjective and physiological effects, depending on the intensity of the stimulation used. To speak about the behavioral and emotional effects of electricity in general and biased ways is counterproductive. The objective effects of ES range from below-threshold to tetanizing and life-threatening shock. When referring to ES, an effort should be made to specify the sort of ES being discussed. Several basic categories are hereby proposed to guide future discussions:

Below threshold of perception
Mild tingling and attention (stimulus recognition)
Annoyance or tickling stimulation
Prickly startle reaction
Discomfort, distress, and escape arousal
Extreme pain and distress

Stress, Distress, and Potential Adverse Side Effects of Electrical Stimulation

Biological Stress and Psychological Distress

Learning is always distressful to some extent, with anxiety and frustration representing important incentives motivating adjustment, just as biological adaptation and the maintenance of stability in change (*allostasis*) are vitally dependent on a dog's ability to generate a stress response. Although stress and distress are not the same thing, some authors appear to treat these phenomena as though they were the same (see Schilder and Van der Borg, 2004). Just as physical exercise produces biological stress while building muscle mass and endurance, short-term stress in the context of training is not necessarily without robust long-term benefits. Psychological distress (anxiety, frustration, and startle) per se is not necessarily an impediment to learning, nor does it necessarily represent a threat to a dog's welfare (i.e., a state conducive to and promoting an adaptive coping style in response to an environmental challenge or threats). Distress is first and foremost a healthy response to an environmental challenge requiring an unaccustomed adjustment. Stress and distress only become problematic when they occur under social or environmental circumstances that prevent a dog from coping (adjusting or adapting) effectively—conditions that may result in various behavioral and biological disturbances as indexed, for example, by allostatic load and overload (Wingfield, 2003).

Dogs exhibit considerable variation in their response to ES. In addition to the electrical characteristics of the e-stimulus event, various behavioral and psychological influences exert significant modulatory effects on a dog's response to ES. Prominent among these influences are habituation, sensitization, and opponent processes (relief/relaxation). The genetic heterogeneity and variation, even among dogs of the same breed, confer upon them a highly variable capacity for coping with aversive stimulation. Vincent and Michell (1996) found, within a population of 227 trainee guide dogs, that 96 (42.3%) were stress prone, a propensity that correlated with a trend toward higher blood pressure and heart rate. Dogs exhibiting a heightened vulnerability to stress will likely respond to shock in a more reactive and stressful way than will dogs less prone to stress.

When coping with a threat or challenge, a dog may show variable signs of anxiety or frustration but become problematically distressed only if the situation proves uncontrollable, whereupon anxiety (the situation lacks predictability) may grow into fear or frustration (the situation lacks controllability) may escalate into anger or aggression. While mobilizing the flight-fight system (FSS), the sympathoadrenal-medullary system (SAM) helps to promote a state of arousal and bodily readiness to react to a situation perceived as dangerous and uncontrollable. A slower opponent regulatory system, the hypothalamic-pituitary-adrenal (HPA) axis, is brought into play by the action of corticotropin-releasing factor (CRF) on the pituitary, stimulating the release of adrenocorticotropic hormone (ACTH) into the bloodstream. ACTH acts on the adrenal cortex to stimulate the release of glucocorticoid hormones (e.g., cortisol), which perform a number of adaptive biological functions within the body and brain. As cortisol enters the brain, it counteracts the reactive emergency state of arousal and begins to restore balance by exerting a general calming effect, including a negative-feedback control over the release of CRF that in turn inhibits the release of ACTH, which in turn decreases the secretion of cortisol, as things are gradually normalized. With respect to the use of aversives in dog training, the dog appears to have evolved antistress and antinociceptive capabil-

ities that enable it to cope with such demands, perhaps mediated by a specialized oxytocinergic-opioid network (Panksepp et al., 1997; Uvnäs-Moberg, 1998) that enables it to cope (flirt and forbear) with significant psychological distress without prompting the activation of the SAM and HPA systems, provided that the distressing event is perceived by the dog as controllable. Dess and colleagues (1983) performed a series of experiments to evaluate the effects of event predictability and controllability versus event unpredictability and uncontrollability on plasma cortisol levels in dogs exposed to shock (7 mA for up to 15 seconds and 5 mA for up to 5 seconds). The dogs were divided into several groups, some of which could escape the stimulation, whereas others received shock regardless of what they did to escape from it. The researchers found that dogs that could control the occurrence of shock by escape exhibited a significantly attenuated cortisol response than did dogs having no control over the shock stimulus.

Among dogs, controllable aversive events may generate signs of temporary distress and precursor submission behaviors, but it is highly unlikely that such events rise to the sort of biological challenge or threat that might pose a significant threat to a dog's welfare or quality of life. Submissive precursor behaviors mediated by the corticobulbar social engagement system (Porges, 2001) are frequently mistaken for fear and evidence of stress. By carefully drawing lines between biological stress, quantified by changes in the release of adrenal steroids, and psychological distress, as indicated by autonomic changes (e.g., heart rate and HRV), one might avoid some of the confusion. Having a set of behavioral markers that might be used to assess biological stress would also be convenient, but until such behavioral markers have been properly validated, the use of ambiguous behavioral signs and ambivalent behaviors to index stress is fraught with the risk of subjectivism (see *Electronic Training and Working Dogs: A Shocking Study*). Beerda and colleagues (2000) have warned that ambiguous "stress behaviors" (e.g., subtle postural changes, oral displacement activities, paw lifting, yawning, and so forth) may lead to false interpretations, unless the behaviors can be closely tied to physiological markers of stress (e.g., cortisol). Salivary samples can be obtained within 30 seconds or so (Kobelt et al., 2003), making such minimally intrusive sampling convenient for verifying the presence of stress. Without physiological markers, the attribution of stress to ambiguous behaviors is unwarranted and interpreting them as indicators of stress lacks scientific support. Changes in cortisol appear to be useful for detecting long-term adverse effects associated with shock in training (Stichnoth, 2002) and may be revealing even in the absence of overt behavioral signs of stress (Vincent and Michell, 1992).

Stress, Traumatic Avoidance, and Laboratory Conditioning with Shock

Evidence for individual differences affecting the way dogs cope with the most severe and debilitating electrical shock has been reported by several researchers. Perhaps the most extreme of these studies was performed by Houser and Paré (1974), who subjected two dogs to a daily regimen of electrical conditioning for 6 months. The dogs were restrained in a Pavlovian hammock, with electrodes delivering a 0.5-second 4.0-mA shock every 20 seconds to a hind leg. Each daily session lasted 3 hours. The dog could avoid the shock and postpone it for 20 seconds, provided it performed at least one key-pressing response during the 20-second period. During the last 2 months of the study, a classical conditioning contingency was superimposed on the Sidman avoidance schedule just described, thereby significantly increasing stress. Every day for 2 months the dogs received seven unavoidable 8-mA shocks lasting 0.5 seconds that were preceded by a 3-minute conditioned stimulus (light). Bear in mind that the dogs had to keep track of the temporal avoidance contingency simultaneously while bracing for the repeated presentation of unavoidable shock. Aside from demonstrating that human ingenuity for cruelty knows no bounds, the study showed that dogs possess a profound adaptive capacity for coping with the most assaultive and stressful circumstances. A dog's

capacity to endure such laboratory conditioning is strongly dependent on individual differences, and the two dogs showed very different patterns of heart rate and cortisol release during the *300* hours of data collection.

Among psychological influences, the amount of control that a dog has over the aversive event directly affects the amount of fear and stress that it will likely experience when exposed to ES. For example, inescapable painful or traumatic shock may produce temporary and perhaps permanent debilitating effects on a dog's ability to cope competently with aversive situations, as well as stimulate a variety of stress-related physiological changes. However, generalizing to the notion that ES is debilitating per se is not justified by the relevant scientific literature. Under laboratory conditioning, dogs have demonstrated extraordinary capacities for coping with severe shock and other forms of traumatizing treatment (Solomon and Wynne, 1953; Kamin, 1954). A worker in Pavlov's laboratory trained a dog to salivate and to show negligible signs of defensive behavior or cardiovascular distress by pairing increasing levels of shock with food, gradually reaching levels of intensity sufficient to burn the skin, emphasizing the extraordinary adaptability that dogs exhibit with respect to electrical shock arranged to predict appetitive gratification:

> The conditioned food reflex was elaborated not from an indifferent agent but from a destructive one evoking an inborn defensive reflex. The skin was irritated by an electric current and at the same time the dog was fed, although at first the feeding had to be forced. A weak current was applied which was later increased to the maximum. The experiment ended thus: with the strongest current, as well as with burning and mechanical destruction of the skin, there could be provoked only the food reaction (the corresponding motor reaction and the salivary secretion) and there was no trace of any interference by the defensive reaction, there were no changes in breathing or heart beat, characteristic of this last reaction. (Pavlov, 1928:341)

The critical issue at stake appears to be the degree of perceived control that the dog has over the aversive event. In the case of classical conditioning where food is associated with shock, the dog may perceive the shock as a controllable event contingent upon it waiting for some brief period after which the shock ends (safety) and food appears (comfort). The loss of control over aversive stimulation appears to increase the risk of inducing problematic cognitive, emotional, and behavioral effects. Littman and colleagues (1964) exposed rats of different ages to five sessions (each at 1 mA for 3 minutes) of continuous inescapable shock and found that shock thresholds and latencies for escape were significantly increased when traumatized rats were tested 1 day later. The adverse effects of uncontrollable trauma were still evident after 2 months.

When Seligman and Maier (1967) exposed dogs to escapable and inescapable shock to test various hypotheses regarding the effects of event controllability and uncontrollability on avoidance learning, they found that adverse cognitive and emotional interference effects and learned helplessness were primarily exhibited by dogs that lacked control over shock, whereas dogs with control over shock were less disturbed by the experience. A yoked design resulted in both groups of dogs receiving identical stimulation, except that the dogs under the escapable shock condition could terminate shock by pressing a panel located next to the head, whereas the dogs in the inescapable group had no control over the shock event. The dogs were restrained in a Pavlovian hammock with holes cut out for their legs, which were immobilized by cords lashed above the feet and tied to the floor. The only difference between the two groups was that dogs in the escapable group could terminate shock by pushing a panel located next to the head. The inescapable group received 64 shocks (6.0 mA), at 5 seconds each, delivered to the pads of their hind feet. During subsequent escape testing, both groups were exposed to 10 trials in which a 10-second conditioned stimulus was presented (a dimmed light), followed by 50 seconds of "severe pulsating shock" (1969:322). The intertrial interval varied from 60 to 120 seconds.

Approximately two-thirds of the dogs (N = 82) previously exposed to inescapable shock showed evidence of impairment in their ability to initiate escape behavior. Dogs that failed to jump over the barrier could be taught to overcome the interference effects of inescapable shock by being repeatedly pulled over the barrier by leash, gradually learning (some requiring 50 trials) to hop over it with the slightest tug and finally do so on their own (Seligman et al., 1968). If the dogs were allowed to rest for 48 hours prior to escape testing, these dramatic interference effects were not observed despite repeated exposure to inescapable shock (Overmier and Seligman, 1967). However, if the inescapable exposure was repeated, more durable interference effects were observed. Seligman and Groves (1970) showed that dogs with a variegated history of prior exposure to aversive stimulation had a greater resistance to the adverse effects of inescapable shock, requiring four blocks of 64 trials in which 5-second shocks were given on each trial for a total of 1280 seconds of exposure to shock in order to establish learned-helplessness effects. In contrast, cage-reared dogs showed a greater susceptibility to escape impairments, requiring two blocks of 64 trials in order to show enduring learned-helplessness effects—lasting at least a week. Caged dogs may receive insufficient opportunities to acquire coping skills, making them more vulnerable to the adverse effects of uncontrollable aversive stimulation. Lessac and Solomon (1969) found that severe isolation lasting for 1 year resulted in escape/avoidance behavior resembling learned helplessness—deficits that were prevented by electrical escape/avoidance training at week 12.

Electrical Stimulation Controllability and Safety

A large body of scientific evidence supports the notion that opponent poststimulation relief and relaxation is an important motivational aspect of escape/avoidance learning. The immediate effect of ES termination is emotional relief, which is subsequently followed by opponent-relaxation effects that develop more sluggishly and automatically over the next 2 to 3 minutes (Denny, 1991). As a result, the cessation of a controllable e-stimulus or its avoidance appears to promote hedonic emotional changes conducive to reward and safety (Denny, 1971). Further, conditioned stimuli associated with shock (S1) or the absence of shock (S2) have been shown to promote differential behavioral changes consistent with the safety hypothesis (Rescorla and LoLordo, 1965) (see *Safety Signal Hypothesis* in Volume 1, Chapter 8). While performing a Sidman avoidance task, dogs increased avoidance responding while in the presence of the excitatory S1, whereas they decreased avoidance responding when the inhibitory S2 was presented. Using a paradigm of classical conditioning similar to that employed by Rescorla and LoLordo, Billman and Randall (1980) confirmed that discriminated excitatory (paired with shock, S1) and inhibitory (not paired with shock, S2) conditioned stimuli also exert a differential effect on cardiovascular activity consistent with preparatory aversive arousal/threat and relaxation/safety effects, respectively. The signaled cessation of shock and partial reinforcement in dogs has also been shown to produce conditioned changes in heart rate consistent with the safety hypothesis (Fitzgerald, 1966; Royer, 1969). Finally, basic learning research with rodents (Galizio, 1999) appears to support the notion that stimuli predicting safety from shock (S2) acquire persistent reward properties that continue after extinction of the avoidance response has occurred. Poststimulation relief and relaxation has been successfully used to treat avoidance-motivated aggression in dogs (Tortora, 1983) and other refractory canine behavior problems (e.g., aggression toward strangers and other dogs) (Schwizgebel, 1992). In combination, the foregoing laboratory work supports the notion that safety in association with the successful escape/avoidance of aversive stimulation may augment the value of social rewards (e.g., petting and praise) used by the trainer to support cooperation and obedience to command. Properly performed electronic training promotes a confidence-building pattern of escape to safety that can be highly beneficial and useful in the context of canine behavior therapy

(see *Escape to Safety versus Escape from Danger* in Chapter 8)

Electrical Stimulation Technology

Electrical stimulation has been used in various ways to influence motivation and behavior. In medicine, ES is used to aid in the control of heart problems, ranging from defibrillators resuscitating a lost heartbeat to pacemakers helping to maintain the heart's rhythm. Intracranial electrodes implanted in various parts of the dog's brain have been used to monitor and modify brain electrical activity and behavior (Himwich et al., 1965; Wagner et al., 1967). Vagal nerve stimulators have been successfully implanted and used to control seizure activity in dogs not responsive to anticonvulsant medication (Munana et al., 2002). Theoretically, certain intractable aggression problems or compulsive disorders associated with sympathovagal dysregulation or temporal seizure activity might benefit from vagal nerve stimulation (VNS), but to my knowledge such devices have not been evaluated for the control of serious canine behavior problems.

The use of ES on the skin has several applications in medicine. ES has been successfully used in acupuncture, as well as other applications for the control of pain, such as transcutaneous electrical nerve stimulation (TENS). Medical stimulators have also been developed to improve muscle tone via high-voltage constant-current stimulation. Several groups of bioelectrical engineers have been working for many years on sensory-substitution applications using electrocutaneous stimulation (ECS) and vibrocutaneous stimulation. These devices are aimed at assisting blind or deaf users or those needing to use prostheses (Kaczmarek et al., 1991). The modern e-collar has benefited significantly from these research and development advances in ECS technology. Perhaps the most common and controversial scientific use of ES has been in the contexts of the learning laboratory (Solomon and Wynne, 1953), aversion therapy (McGuire and Vallance, 1964), and behavior-modification programs (Lovaas et al., 1965; Lovaas and Simmons, 1969). Researchers investigating fear and pain have also made considerable use of ECS (Tursky, 1973). In combination, many hundreds of studies have been dedicated to the sensory, autonomic, emotional, and behavioral effects of ES for motivating and controlling behavior (Campbell and Masterson, 1969), making ES the most carefully and exhaustively studied aversive stimulus available for use by dog trainers. An early radio-controlled device designed for laboratory conditioning with dogs used a harness-and-collar arrangement. The collar produced a 30-mA current (1000-V peak amplitude output) delivered through electrodes positioned on the dorsal surface of the dog's neck (Caldwell and Judy, 1970). One of the earliest radio-controlled devices explicitly designed for dog-training purposes appeared in the 1950s (Cameron and Hopkins, 1955). The radio-controlled receiver delivered a high-voltage, low-amperage current of electrical charge to the shoulders of the dog via electrodes fastened to a harness. The device produced one level of stimulation and was designed primarily to punish undesirable behavior.

Numerous electronic training aids have been developed in recent years incorporating a mild electrical or spray stimulus (e.g., aerosol citronella) to modify dog behavior. These devices can be divided into two general categories, depending on whether they are activated by a trainer controlling a radio transmitter or directly activated by the dog's behavior. Radio-controlled electronic devices are used to deliver various signals (e.g., tones, clicks, or vibrations) and aversive stimulation via a receiver attached to the dog's collar. Activation of the collar is controlled by a hand-held transmitter that provides the trainer with precise control over the presentation of both conditioned and unconditioned aversive stimuli at a distance. In addition, some collar systems include a reward tone or click that can be paired with successful escape/avoidance or the presentation of appetitive-positive or social-positive reinforcement (e.g., food or petting). Most current products permit the user to adjust the level of stimulation from a nearly imperceptible level or annoying tingle

or tickle to a strongly aversive prickly twitching sensation.

Behavior-activated electronic training collars are most commonly used in applications involving outdoor containment and the control of excessive barking. Unlike radio-controlled electronic training aids, behavior-activated collars are not dependent on the presence of a human operator. In the case of containment systems, both conditioned (warning tone) and unconditioned (electrical or spray) stimulation are delivered automatically as the dog approaches an underground wire that encircles the property. The wire boundary forms a closed loop with a circuit box that transmits a radio signal to the receiver collar worn by the dog. Whenever the dog approaches within a certain distance (approximately 2 to 10 feet) of the boundary line (warning-signal field), a tone stimulus is activated that is immediately discontinued if the dog backs away; however, if the dog encroaches further into the warning field, an aversive electrical or spray stimulus is delivered. In the case of bark-activated e-collars, a microphone or a vibration sensor that makes contact with the dog's neck closes a circuit causing the collar to deliver a brief e-stimulus. Another device that has become popular with some trainers and behaviorists in recent years uses aerosol citronella sprayed from a collar. When activated by barking, the solenoid valve releases an aerosol spray directed up toward the dog's head. Unfortunately, the velocity of spray flow and the intensity of the odorant delivered cannot be adjusted to meet specific training needs. The device does, however, allow the user to deliver a short or long spray stimulus.

Many other electronic devices are in use to control dog behavior. These gadgets include electronic systems designed to protect specific areas of the house against intrusion or destructiveness. One device, used to protect furniture and other surfaces in the home, delivers static shock via an electrified mat. Other devices depend on the generation of loud audible and ultrasonic sounds to deter various actions. Some devices emit a loud high-pitched tone that is activated by motion, body heat, or vibration. After a variable period (ranging from 2 to 20 seconds), the sound stimulus shuts off and resets. Although loud auditory stimulation appears to work well on certain problems, ultrasonic devices do not appear to be as efficacious (Blackshaw et al., 1990). In comparison to electrotactile stimulation, loud sounds appear to be significantly less aversive (Campbell and Bloom, 1965).

Radio-controlled Electrical Stimulation

Over the past decade or so, electronic training has become increasingly popular among dog trainers for establishing increased control and reliability when a dog is off leash and for treating a variety of behavior problems. The wide acceptance of electronic tools by the dog-training community has been in part the result of significant design improvements in the size, adjustability, reliability, and safety of e-collars. Electronic devices are also becoming increasingly affordable. The e-collar's ability to deliver a consistent and precise ES at a distance makes the device extremely attractive and useful. Recently, relatively inexpensive collars have come to the market that are small, lightweight, and loaded with sophisticated features, including the ability to increase or decrease the level of stimulation from the transmitter instantly and in real time by turning a dial. This feature enables a trainer to accurately match the stimulation level to an individual dog's sensitivity and temperament. These electronic training collars deliver a relatively consistent and measured level of aversive stimulation, ranging from a tickle, tingle, twitch, or prickly twinge to a highly aversive electrical event that produces significant discomfort and startle but without risk of producing physical injury or pain. These devices also feature the ability to deliver a continuous stimulus lasting as long as the button is held down or until the receiver unit automatically shuts off and resets after approximately 8 to 12 seconds. Alternatively, a stimulus lasting a fraction of a second can be selected for the delivery of precise stimulation and prompting effects similar to that produced by leash checks. These various operational features satisfy the technical requirements for effective

punishment and negative reinforcement, and give the trainer fingertip control over the timing, intensity, and duration of aversive stimulation. In addition to the delivery of a controlled e-stimulus, various tone and vibratory stimuli can be delivered in close pre-event and postevent association with ES, so that conditioned positive and negative reinforcers, punishers, and other signals (e.g., safety signals) can be developed and used to facilitate electronic training objectives. In combination, these various features help to minimize the amount of aversive ES needed to reach training objectives while maximizing a trainer's creative control over the delivery, intensity, and duration of aversive stimulation.

The effective use of ES requires significant skill and understanding of the training process. Ideally, such devices should be used only in the context of supervised training and behavior modification. Once a foundation of reward-based training is in place incorporating positive reinforcement, structured play, and various conventional directive efforts, remote electronic enhancement can be employed to achieve improved control at a distance (Tortora, 1982). Electronic training is also used to establish basic control that is not otherwise efficiently obtained by reward-based techniques alone. Once the training objectives are achieved via electronic procedures, positive reinforcement is used to maintain and generalize the behavior. Combining escape/avoidance training with positive reinforcement appears to optimize conditioning effects. For example, Franchina (1969) found that trained behavior is enhanced by exposing animals to a contingency in which target responses are followed by both shock offset and the presentation of a food reward. In the case of animals where the food reward was omitted but the shock-escape contingency held constant, the performance of animals declined below levels attained by the use of negative reinforcement alone. These findings stress the importance of combining both positive- reinforcement and negative-reinforcement procedures to optimize performance reliability. Despite a significant potential for misuse and abuse, electronic training tools provide significant advantages for skilled users (Table 9.1).

Electronic training is efficacious and warranted in situations where enhanced remote control of a dog is needed or when problem-solving objectives demand accurate, timely,

TABLE 9.1. Advantages of electronic devices for delivering aversive stimulation (ES, electrical stimulation)

ES is the most thoroughly studied aversive used in animal behavior and learning research.
ES at the levels used in dog training is virtually harmless, giving no evidence of lasting pain, tissue damage, or psychological trauma.
ES has many aversive control applications, ranging from escape/avoidance training (negative reinforcement) and suppression (positive punishment) to aversive counterconditioning.
ES intensity can be adjusted from very low and barely perceptible stimulation up to startling and highly aversive levels, thereby accurately matching a dog's specific needs and temperament.
ES duration can be precisely regulated, ranging from a fraction of a second to several seconds long.
ES can be delivered instantaneously at various distances from a dog.
ES can be delivered without the owner being present or being directly associated with the owner as its cause.
ES training appears to depend more on startle and annoyance than pain.
ES training techniques are highly compatible with instrumental training procedures (e.g., clicker training), enhancing performance, reliability, and assisting in problem-solving activities.
ES training techniques facilitate safe and reliable off-leash control and recall training.
ES training aids are relatively easy to use.

and remote aversive stimulation. Although radio-controlled e-collars are inappropriate for use as the initial or primary means for establishing basic obedience control, no comparable techniques or tools currently available can match the efficacy and safety of the e-collar for establishing safe and reliable off-leash control. In any case, humane electronic training procedures employ a minimal level of aversive stimulation to achieve behavioral objectives. Most dogs are highly responsive to ES set at levels that are barely perceptible to human touch. For the vast majority of training objectives, stimulation never exceeds a painless tingling or occasional twitching or pricking level. When properly used, electronic stimulation produces rapid and steady avoidance learning or, when applied at higher levels of stimulation as a punitive stimulus, suppression is often immediate and lasting. If minimizing the intensity, duration, and frequency of aversive stimulation during training is recognized as a significant factor in the definition of humane dog training, the radio-controlled e-collar must then be ranked as one of the most humane dog-training tools currently available.

Although most obedience-training objectives can be adequately achieved using a combination of reward-based methods and directive techniques, such approaches may not be sufficient to achieve effective control over high-spirited dogs under circumstances of increased motivation or distraction. Maintaining control under such circumstances may be especially problematic with adult dogs that have learned to evade the owner or run out of control when let off leash outdoors. Further, some dog owners may simply lack the physical strength and coordination to effectively use a leash and collar, long line, or throw tools. For example, elderly dog owners may be challenged beyond their means when faced with the behavioral excesses of an overly active dog. For such owners, leash and collar or halter restraint may not provide adequate means of control. Furthermore, despite the most conscientious reward-based training efforts, such training may not adequately curb canine appetites and excesses to a point of ensuring safe interaction with a fragile or physically disabled handler. Under such circumstances, electronic training aids may prove extremely useful and beneficial. Properly introduced, surprisingly low levels of ES can cause otherwise inattentive and uncooperative dogs to learn rapidly to comply with owner demands and directives that previously went unheeded. Basic control elements such as sit, down, stay, and come can be quickly enhanced and made more reliable by brief exposure to escape/avoidance training involving LLES. A combined approach incorporating both positive and negative reinforcement optimizes training efforts (see *Behavioral Equilibrium*). Optimization results in a rapid increase in performance reliability and fluency over a wide range of motivational and environmental conditions.

First and foremost, electronic training provides efficient means to enhance attention and impulse control under adverse environmental and motivational conditions requiring close timing of aversive stimulation, especially when a dog is off leash. The e-collar can be effectively used to induce a dog to perform more reliably under challenging situations in which it is most likely to hesitate, refuse, or disobey by engaging in behavior incompatible with training objectives. Obviously, securing a dog's attention provides a powerful means for initiating impulse-control training. In combination with attention training, training efforts that focus on relevant intentional movements that anticipate the loss of impulse control help to facilitate more reliable behavioral control. Establishing control over orienting behavior and intentional movements requires a high degree of precision. If a dog is kept in close proximity on leash or otherwise restricted, various nonaversive tools and techniques may suffice; however, with the dog at some distance away, operating under the influence of natural environments and contingencies of reinforcement, nothing provides the required control and fine-tuning more efficaciously than an e-collar. Most dogs can be trained effectively without electronic enhancement, but in cases in which dogs exhibit dangerous behavior that risks injury to itself or others, intervention with electronic training is definitely a viable and humane alternative to traditional punishment techniques.

As is discussed in the section *Electrical Stimulation and Aggression*, electronic training and enhancement of basic-training modules and routines may play a valuable therapeutic role in counteracting established patterns of inappropriate and reactive behavior occurring under aversive or threatening situations. Highly structured and systematic training using ES may help to enhance a dog's social competence and confidence by teaching it that it can control (avoid or escape) aversive events by means of cooperative behavior, thereby potentially reducing the likelihood of maladaptive aggression or panic responses when confronted with adversity. Of course, using electrical training techniques to control potentially aggressive dogs requires that trainers possess significant knowledge and experience with such dogs and a working understanding of the benefits and hazards of electrical training. Inappropriately painful or poorly timed stimulation may make such problems worse or elicit an aggressive response (Polsky, 2000). Radio-controlled ES has the advantage of minimizing the need for direct manual control of an aggressive dog—a valuable asset in the case of dogs prone to attack when touched or handled.

Behavior-activated Electronic Training

Citronella-spray Collars

Bark-activated citronella collars appear to be effective for controlling certain barking problems (Wells, 2001) but are not necessarily less aversive to dogs than are electronic counterparts. One study comparing the punitive effects of a citronella collar with an electrical device reported that the citronella treatment was more effective than shock in suppressing nuisance barking in dogs (Juarbe-Diaz and Houpt, 1996). The authors found that 89% of the owners using the citronella collar to control excessive barking reported satisfactory results, whereas 44% of owners using an e-collar reported satisfactory results. Unfortunately, the study was limited to nine dogs, and the authors may have been biased with respect to citronella devices (Wells, 2001)—a bias that one of the authors appears to acknowledge in another context (Juarbe-Diaz, 1997). Given the acuity of a dog's olfactory sensibilities, it is not surprising that a potent aerosol odorant sprayed near a dog's nose and mouth would be aversive. What is surprising, however, is that the citronella device outperformed the electronic one—a finding that one should view with some skepticism, at least until a larger controlled study is performed and the findings confirmed. Although the citronella odor may be annoying to dogs, bark-activated spray devices appear to depend primarily on the effects of startle, with the odor of dilute citronella playing a secondary role. Citronella scent delivered without spray does not appear to suppress barking, but the scent may become an inhibitory stimulus as the result of aversive conditioning.

Recent studies seem to indicate that the citronella scent may not play a significant role in the inhibition of barking. Beaudet (2001) found that both scented and unscented spray collars worked about equally well to suppress barking, with 85% of owners reporting satisfaction with the citronella-scented stimulus versus 80% satisfaction with the unscented stimulus (N = 33). Similarly, Moffat and Landsberg (2001) have shown that unscented spray collars can produce a significant reduction in barking, comparable to that produced by citronella-scented collars (78% improved or controlled with citronella collars versus 57% improved or controlled with unscented collars; N = 36). The hiss produced by spray collars may be preferentially processed by the amygdala, eliciting unconditioned fear and startle. In addition, the amygdala is a primary destination of olfactory inputs, preparing and enabling a conditioned aversive association between a novel odor and startle to develop rapidly.

Bark-activated citronella collars produce approximately 15 to 25 gradually diminishing spray bursts until the spray reservoir is depleted—an operational limitation that habitual barkers may learn to exploit. Given the tendency of dogs to habituate to odors and noises, it is reasonable to assume that repeated bursts of citronella spray may progressively produce less of an effect on dogs. The effect of habituation may be significantly

more troublesome in situations where a dog is left alone and exposed to a high level of bark-evoking stimulation. Along these lines, Wells (2001) has reported that a significant amount of habituation does occur in response to repeated spray stimulation. Her study indicates that, after producing a pronounced initial reduction in barking, dogs gradually habituated to the spray event—an effect that continued during the 3-week treatment program. Interestingly, she found that intermittent treatment (dogs wearing the collar every other day) produced a more lasting suppressive effect over nuisance barking than did the continuous treatment program. Both the continuous and intermittent treatment groups were exposed to bark-provoking stimulation for 30 minutes a day. In addition to a rapidly depleted spray reservoir, a problematic feature of citronella devices is microphone activation. Ambient noises, including the barking of nearby dogs, may activate the devise, thus exposing the dog to inappropriate and noncontingent punishment—apparently a fairly common complaint (Juarbe-Diaz and Houpt, 1996). Also, under outdoor conditions, the spray may be affected by wind and other influences, perhaps making it less effective for such use. Finally, citronella spray as an olfactory deterrent may be inappropriate for dogs used for tracking, search and rescue, or other activities requiring sharp olfactory abilities, since repeated exposure may potentially blunt olfactory acuity. A major advantage of the citronella-type collar is that it does not depend on prong-to-skin contact to deliver stimulation, thereby avoiding unnecessary irritation and discomfort to dogs with sensitive skin.

Electrical Bark Collars

The sustained noise generated by multiple dogs barking in kennel situations commonly exceeds 100 decibels (dB) and often reaches levels as high 125 dB—a range that can damage both human and canine hearing (Sales et al., 1997). The noise associated with excessive barking can hurt ears, and it can harm neighbor relations and lead to legal consequences involving citations, fines, and eviction notices. These pressures can cause a dog owner to take extreme measures, such as relinquishing the dog, resorting to severe punishment, or employing inappropriate restraint procedures. Most dogs can rapidly learn to inhibit excessive barking after the contingent delivery of a brief e-stimulus presented in close association with the barking action each time that a dogs barks (Arguello, 1986). Bark-activated collars can be adjusted to match a dog's temperament and specific behavioral needs. Some devices provide a brief obligatory intertrial interval, during which barking or yelping does not activate the collar. One device also keeps count of the stimulations delivered, providing a useful source of data. A voice-activated recorder can also be used to keep track of barking activity. Unfortunately, not all bark-activated collars perform reliably, and only the highest-quality collars should be selected for use in the context of behavior therapy. Although some collars are designed to be relatively insensitive to nearby loud noises (e.g., other dogs barking) and impact vibrations, certain cheap collars sold in pet stores are activated by being bumped or when scraped when the dog lies down or moves about. This defect can be especially problematic and harmful with dogs confined to crates. Some of these problems can be prevented by encasing the collar in a thin protective foam sheath or by covering it with a bandana worn by the dog. Proper control of excessive barking depends on an accurate and detailed evaluation of underlying causes. In addition to performing behavioral assessment, the trainer should explore minimally aversive behavior-control techniques and reward-based strategies before opting to use bark-activated ES (see *Barking* in Chapter 5). The introduction of a bark collar should not be decided casually and never without giving serious thought to potential side effects that might result from bark-activated ES. Certain behavior problems that present with excessive barking, such as separation distress and panic (see *Electrical Stimulation and Excessive Barking*), may be exacerbated by aversive electrical procedures.

Ideally, whenever behavior-activated electronic devices are used in the context of behavior therapy, preliminary radio-controlled training incorporating LLES should be per-

formed with the goal of training the dog to *perceive* that it has control over the occurrence of the ES. Preliminary training should begin with the enhancement and refinement of various basic modules and routines, especially attention and orienting responses, sit, stay, back and wait, slack-leash walking, and recall training. In addition, barking behavior should be brought under stimulus control, whereby the dog learns to bark on command and to stop barking on command. Stimulus control is established via reward-based discrimination learning. Training a dog to bark on command appears to increase its ability to autoregulate bark-related arousal and impulses without becoming overly inhibited. Once basic stimulus control over the bark response is established, a vibratory stimulus is used in conjunction with a stop-bark command, followed by LLES alone or LLES embedded in a brief continuous vibratory stimulus overlapping undesirable or off-cue barking behavior. As the barking activity ceases, the stimulation should also immediately stop, followed by social and appetitive rewards. On every occasion in which the dog barks inappropriately, the e-stimulus is delivered along a staggered intensity gradient until a level is reached that instantly suppresses the bark response and results in sustained bark avoidance, thereby approximating the level of stimulation needed by the bark-activated collar to maintain the bark inhibition. The goal is to establish a level of ES sufficient to inhibit barking but without causing the dog undue discomfort or distress. Before transitioning to a bark-activated collar, transfer training and tests are performed with the dog left in various bark-stimulating situations while wearing a radio-controlled collar. Many potential problems are avoided by slowly introducing ES via radio-controlled training before advancing to the bark-activated stimulator.

Electronic Containment Systems

The most common use of behavior-activated electronic devices involves ES to train dogs to stay within the confines of a property boundary. The exact number of electronic boundary systems in current use is not known, but one large company alone has reported installing some 500,000 units from 1982 to 1997 (Polsky, 2000). Some electronic boundary systems use a relatively strong e-stimulus that may cause some dogs to experience significant pain, fear, and distress. Dogs inappropriately exposed to boundary ES may show intense fear and avoidance of the yard, especially when a young dog has been denied access to the yard for play and training prior to the event. Prior safe exposure to the yard appears to promote latent inhibition and conditioned associations incompatible with fear (comfort and safety). The first experience of some dogs to being walked on leash by a stranger is one in which they are pulled into the boundary field and forced to experience intense ES by a containment-system salesperson or installer. As a result of such exposure, such dogs may show strong generalized anxiety or reactive behavior whenever they are put on leash, along with a lasting wariness or autoprotective behavior toward strangers encountered near the boundary, especially those that might reach for or attempt to restrain the dog. In cases where stimulation occurs while the dog is in the presence of two persons, one familiar and one unfamiliar, the event shows an associative affinity for the unfamiliar person, even though the dog might actually be in a slightly closer proximity to the more familiar person at the moment of stimulation. The resulting social fear response toward the unfamiliar person may be highly durable and resistant to extinction and counterconditioning efforts. Adventitious ES occurring in association with safe activities, such as play or tagging along with children, can exert a profound loss of trust and security that may compromise a dog's ability to feel safe or to relax when engaged in those activities. Dogs exhibiting problematic temperament traits (e.g., excessive fearfulness or aggressiveness) should not (or only cautiously) be contained electronically, because in some dogs ES may elicit global panic reactions or an increased risk of directing aggressive behavior toward persons or animals entering the property. However, even dogs without an established history of aggressive behavior or fearfulness, *may*, under certain circumstances, become aggressively

aroused when electrically stimulated (Polsky, 1998 and 2000). Obviously, particular caution should be used when employing such devices indoors, where there exists an increased likelihood of stimulation in close proximity to people. To reduce the stress associated with electronic containment, the fenced area should be large enough to allow the dog to move about freely without fear of triggering ES.

Preliminary enhancement of basic modules and routines with a radio-controlled collar is useful and avoids many of the present pitfalls associated with boundary training. Such training instills positive prediction-control expectancies and establishing operations conducive to a competent escape-to-safety pattern of proactive adjustment to ES. After a basic introduction to attention, stay, back and wait, halt-stay, and recall training, boundary training is introduced using these basic modules, as needed. Eventually, the boundary collar can be fastened in combination with the radio-controlled collar in order to establish appropriate conditioned escape/avoidance responses, beginning with LLES and then gradually introducing additional distractions and increasing intensity as required to maintain and enhance the avoidance response. The idea is to train the dog to perceive the LLES as a controllable event (e-stimulus) or cue (e-signal) predictive of safety, provided that it turn or back away in response to the warning signal. Initially, the dog is kept on a long line so that any hesitation or contrary response can be immediately countered with appropriate prompting or redirection. As training progresses, failure to turn or back or turn away is followed by an appropriately intense event to establish reliable deterrence. Throughout the process, the trainer should provide constructive support and offer the dog a haven of safety and play as it learns to respond to boundary warning tone as an avoidance signal. In addition to learning that the boundary ES is controllable, the dog must be given sufficient exposure to play and rewarding activities in the yard to make it a viable escape-to-safety destination. In addition to learning the boundary rule, various important secondary inhibitory lessons (e.g., all-stop, stop-change, and go/no go) and enhanced impulse control can be acquired in the context of boundary training, thereby further maximizing the potential add-on benefits that might be obtained through the process.

Puppies at 16 to 20 weeks that are destined to undergo inhibitory boundary conditioning probably stand to benefit most from the gradual introduction of controllable ES via preliminary radio-controlled training using LLES. During preliminary training, the trainer can get an accurate idea of the amount of ES needed to establish reliable behavior-activated boundary control. In addition to the benefits of a radio-controlled introductory phase, emotional distress associated with boundary training can be reduced significantly by incrementally introducing the deterrent level of ES through steps of appropriate exposure and training. If the containment system lacks sufficient adjustability to match the output level of the e-collar to the particular needs of the dog, a set of insulated resistors or an adjustable potentiometer might be used as a voltage divider to achieve the desired adjustability. Any modifications of this nature to an e-collar device should be performed under the advisement of an electrical technician and only after consulting with the manufacturer for any potential incompatibilities. Finally, unless extraordinary circumstances warrant otherwise, electronic boundary training in earnest should not be commenced until the puppy is 6 months of age.

Although electronic containment systems are effective when properly installed and maintained, whenever possible a physical fence is preferable to an electronic one for confining dogs. In addition to keeping the dog in the yard, a physical fence keeps other dogs and people out. With dogs that jump over or dig under fencing, an electronic fence can be installed to discourage such escape behavior. To be effective, e-collars must be snugly fitted to ensure that both electrodes make contact with the dog's skin. This operational feature can be a source of significant discomfort, especially if the collar is kept on a dog for long periods. After prolonged and continuous wear, the skin may become irritated or experience significant tissue damage

(contact necrosis) (Polsky, 1994). Another problem becomes evident only after a dog escapes from the yard and attempts to get back inside, whereupon it is stimulated and caused to flee the property. In neighborhoods where many of the same electronic containment systems are installed, the roaming dog may be repeatedly stimulated, perhaps causing it to seek safety in the worst possible place: the middle of the road! Hopefully, manufacturers will design systems in the future that allow the dog to reenter the yard and devise safeguards against extraneous stimulation by other containment systems. In addition, a telephone paging system that automatically calls and warns the owner, or triggers an alarm within the house, whenever the dog escapes the yard would be a valuable enhancement of such systems. Given the risks of escaping from the yard and the potential danger posed by other dogs freely entering the property, containment systems should include video surveillance for observing the goings-on in the yard. The cable feed could be put into the ground at the same time the containment system is installed. There is an obvious marketing angle here that might be of interest to the containment-system distributors, whereby the combination of containment and surveillance arguably provides a combination of enhanced home security and safety benefits. Such video capability would also offer an enhanced means for keeping a closer eye on children playing in the yard. A miniaturized rf-video camera and microphone built into the collar itself would also be of immense utility. Finally, video surveillance is an extremely useful means for studying dog behavior as well as addressing a variety of common outdoor behavior problems with the aid of radio-controlled spray or ES. Inexpensive two-way radios often have a variety of tones and voice-transmission capabilities that can provide a flexible communication interface when the receiver is placed at a fixed location such as near a door or when it is attached to the dog's collar.

Dogs that repeatedly run through electronic boundaries are a potential threat to themselves and to the public safety. There are several causes associated with the failure of such containment systems:

- Damage to the boundary wire
- Inoperative transmitter or receiving collar
- Worn-out batteries
- Improper fitting of the collar
- Improper training

Of this group, the leading cause of failure appears to stem from improper training. In one case, an owner deliberately encouraged a dog to run across the boundary field by calling and cajoling it from the other side, with the dog held on leash by another family member. The dog eventually pulled into the field and reached the owner, whereupon it was pulled back through the field and into the yard as punishment. The dog subsequently exhibited pronounced submission behavior (crawling on her belly, rolling over, and hunching up tightly) when approached by anyone coming into the yard. The dog also showed increased submissive-type urination when greeting visitors at the door. In another case, a dog learned to run through the field after children were instructed to run back and forth across the boundary, with the goal of proofing the inhibition. Other dogs inappropriately exposed to boundary training while off leash have succeeded in escaping from a yard after taking several e-stimulations while running wildly around the yard in a panic, until they finally dash headlong through the field. Many have learned to run through the field while pursuing another dog or while chasing wildlife off the property. One dog was strongly tempted by the lure of livestock kept by a neighbor. The dog would periodically break through the boundary to harass the animals, after which he would return home and wait for the owner to turn off the system so that he could get back inside the yard. In some cases, dogs sharing a residence may follow one another through the boundary. In one instance, a male and female pair occasionally escaped from the yard to jolly about in the neighborhood. On one of these occasions, the family was devastated when they learned that both the dogs had been killed while attempting to cross a four-lane highway near the home. Other sorts of problems peri-

odically involve more idiosyncratic behaviors and causes. In one of these exceptional cases, a dog developed an odd habit resembling learned helplessness, whereby he would stand in the stimulation field shaking stoically and unable to back away or to move forward through the boundary without the help of a family member who had to physically pull the dog back out of the field. This particular dog apparently experienced the e-stimulus around its neck as an inescapable event. Another dog learned to habitually run through the boundary after she had been equipped with a bark-activated collar. Prior to this change, the dog had never broken through the boundary and had learned to closely hug the warning field, from where it persistently barked at other dogs and passersby. Once equipped with the bark collar, the dog began to run out of the yard whenever the collar was activated, perhaps confusing the bark-activated ES as an uncontrollable stimulus coming from the containment system. After a while, the barking behavior stopped, but the dog continued to run through the boundary, even though she received a strong e-stimulus on each occasion.

Dogs that habitually run through the warning and stimulation field appear to have learned an escape/avoidance strategy that is incompatible with containment. Since the act of running over the line ultimately terminates stimulation, the sequence undergoes significant reinforcement every time the dog succeeds. The situation is compounded if the dog attempts to return to the safety of the yard, since the collar is activated a second time. Instead of backing away from the field in response to the warning signal, these dogs acquire an opposite habit whereby they attempt to charge through the field as quickly as possible. In cases where an intractable escape habit has been well established and retraining has failed to improve a dog's response, a special procedure may be useful. A 30- to 50-foot nylon rope is secured to some stationary object and attached to the dog. The stationary line should be set up near locations where the dog has habitually escaped. The rope should be arranged to give the dog enough room to activate the warning field, but prevent the dog from going beyond it. During such training, a radio-controlled collar is used in combination with the containment collar to enable the trainer to apply sufficient ES to deter inappropriate escape. At such times, the stationary line can be used to pull the dog out of the warning field, if necessary. As a result of the foregoing procedure, the inappropriate escape response is thwarted, making retreat into the safety of the yard the only escape option available. Once it is evident that the dog has learned the appropriate avoidance response, various proofing procedures should be performed to further reduce any risk that the dog will charge through the boundary in the future. Dogs that continue to run off the property despite such additional training and deterrence efforts are not good candidates for such confinement.

The use of electronic containment systems for indoor behavior control and restriction should be seriously reexamined with regard to behavioral and social considerations. Although one practitioner has suggested that an indoor ES delivered by such systems can be useful as a means to "protect children from pets and help orchestrate space sharing by pets" (Overall, 1997:288), electrical boundary training indoors can produce significant fear and consequently risks generating reactive behavior in association with approach-avoidance conflict and anxiety, especially around locations where the collar has been activated in the past while the dog was approaching, following, or playing with a family member or another companion animal sharing the household. Defining a property boundary by means of ES seems to be of a radically different nature than training a dog to avoid following family members within the context of the home. Further, given the possibility that boundary-activated devices may elicit aggression in some emotionally reactive and predisposed dogs (Polsky, 2000), the use of indoor electrical barriers to control the movements of dogs likely to show an escalation of aggression in response to ES should be avoided. Indoor electronic containment might be considered in some situations involving dogs that exhibit persistent house-training problems or destructive behaviors, but only after conventional training efforts have been attempted and

failed to train the dog to stay out of forbidden parts of the house, and then only when gates or doors are not practical as the primary means of confinement. Indoor electronic containment may be useful for the control of some problems involving cat chasing and harassment; however, with highly motivated or aggressive dogs, electronic fencing does not provide a fail-safe barrier and should not be used to contain dogs with a history of attacking cats. Finally, properly performed electrical training minimizes associative linkages between the aversive event and the trainer, while encouraging the dog to seek comfort and safety from the owner in association with postevent relief, relaxation, and various rewards.

Caution: The quality of radio-controlled training collars and containment systems varies greatly, requiring that prospective users research the available products to ensure that the system selected is reliable, effective, and humane. Malfunctions resulting in the delivery of uncontrolled ES are uncommon; nonetheless, and despite numerous improvements over the years, no electronic device is entirely fail-safe. Further, not all radio-controlled and behavior-activated electronic training devices provide the same level of safe operation and adjustable stimulation. The quality and "feel" of ES vary among the devices available, with the best products producing a pulse that minimizes pricking and stinging effects. Professional use of such products demands careful attention to the functional fitness and humaneness of the electronic training aids selected. A number of manufacturers have emerged as leaders in the field of electronic training, and professional trainer/behaviorists are well advised to use only those products that offer the highest standards of operational reliability and incorporate low-level stimulation. Selecting from systems that feature rechargeable batteries in both the transmitter and the receiver unit—ultimately a wise selection criterion given the cost of replacement batteries for such devices—significantly narrows the field of possible collars from which to choose. Electronic training devices that produce excessively painful or traumatic shock should be avoided, as should techniques calling for such stimulation.

Basic Training and Enhancement

Electronic training is most effective when it is used to enhance basic modules and routines previously shaped by means of conventional reward-based training. Ideally, the trainer performs introductory electrical training and gradually transfers control of the transmitter to the owner as a basic understanding of the process developed. Most dogs show little or no emotional reactivity or signs of distress to LLES. Although they may find the stimulus annoying, they are not usually frightened by it. Initially, some dogs may exhibit very minor and transient signs of alarm in response to LLES—signs that rapidly habituate and give way to increasing confidence and relaxation as they learn to control the electrical event. Although the vast majority of dogs appear to be highly receptive and responsive to electronic training, some may exhibit an adverse response to ES. Dogs that show signs of reactive aggression, fear, persistent anxiety, insecurity, or depression in response to ES are not good candidates for such training. Also, dogs exposed previously to electronic containment training may exhibit signs of hypersensitization and problematic escape and avoidance behavior in response to LLES. Aside from brief phantom biting and mouthing movements in the direction of the collar, the author has never observed a dog react aggressively toward a person or another dog in response to radio-controlled ES. However, reactive aggression has been reported in association with electronic containment systems (Polsky, 2000). Also, Beaudet (2001) mentions a Jack Russell terrier that appeared to become "mad" when sprayed by a bark-activated citronella collar, causing it to bark more when corrected by the device. Although reactive aggression appears to be relatively rare, such undesirable behavior should be considered a risk in dogs showing unstable temperaments or a standing history of aggressive behavior, where ES is delivered while the dog is in close proximity

(particularly while making physical contact) with a person or another dog.

For dogs showing insecure behavior in response to LLES, electronic training can be introduced in combination with vibrotactile stimulation and target-arc training. A vibration stimulus is paired with an established target-arc stimulus in order to facilitate a safe preemptive bias toward the stimulus while habituating inappropriate aversive responses to the stimulation. The lowest level of ES is gradually introduced by embedding it within the vibration stimulus, thereby amplifying the orienting response, which is followed by a click and a flick of the right hand. Such dogs are given basic radio-controlled training that shadows previous reward-based training, especially orienting and recall modules and routines, until the dog shows a highly competent and confident response to conditioned signals and LLES. Successful responses are bridged and rewarded with food and other rewards presented on a schedule conducive to positive prediction error (surprise). Signs of fearful behavior are interrupted at the earliest point by evoking a target-arc response, followed by an orienting "Good!" (or a click), hand flick, and reward. The evocation of strong escape/avoidance behavior should be avoided, but such behavior that does occur should be blocked with a leash or long line worn by the dog at all times during the initial stages of training. At such times, the dog is turned around (with the long line if necessary), whereupon "Relax" is spoken just as the e-stimulus is turned off. The most common cause of excessive reactivity is sensitization resulting from previous traumatic exposure to electronic training or exposure to sensitizing aversive events (e.g., bark-activated and boundary-activated collars). Electronic training procedures using HLES should be performed under the supervision of experienced trainers who are knowledgeable concerning the benefits and potential risks associated with safety training.

Attention Training

Most problems necessitating electronic intervention stem from attention and impulse-control deficiencies. Electronic enhancement of attention and orienting behavior is introduced in the context of moderate environmental distraction with the dog on a leash or a long line. A continuous low-level pulse is delivered that is sufficient to get the distracted dog's attention but without evoking startle or evidence of distress. The attention-controlling effect of ES is attained in many dogs at very low levels of stimulation, often imperceptible to human touch; however, since dogs differ with respect to their sensitivity to ES, some may require a significantly stronger level to motivate an attentional response, especially when acting under the influence of strong distractions. Whatever the case, it is critical that ES levels be precisely calculated and controlled to match an individual dog's specific needs, circumstances at the time of stimulation, and the training objectives. Consequently, only electronic training collars that deliver a finely adjustable and reliable e-stimulus, ideally in combination with vibrotactile capability, should be used for such training purposes. As the e-stimulus is delivered, a smooching, squeaker, or whistle sound is made to attract the dog's attention. If the dog fails to orient toward the trainer as the ES continues, it is prompted with the long line to turn its head. As the dog turns, conditioned negative reinforcement (S^{r-}) (voice, click, or tone) is timed and presented to occur just before the e-stimulus is discontinued (Figure 9.1). The S^{r-} identifies the specific behavior that turns off the e-stimulus (escape phase), and, when presented in association with the controlling discriminative stimulus, the S^{r-} signifies that the response successfully avoided the aversive event. In the latter case, the S^{r-} not only serves to reinforce the avoidance response, but its presentation predicts safety from aversive stimulation. Several layers of reward are associated with the successful control of aversive motivational incentives.

Since the termination or reduction of aversive stimulation is perceived as a rewarding event, actions and stimuli paired with the discontinuation of ES gradually acquire reward value of a positive nature—that is, the dog will work to produce them—helping to explain the power of conditioned negative

reinforcement to support avoidance learning. In addition, successful escape promotes rewarding associations with social and contextual stimuli paired with successful escape-to-safety behavior, and such stimuli (conditioned safety signals) acquire potent motivational significance for the dog (e.g., praise). As opposed to escape-from-fear associations, associations acquired during escape to safety may possess significant reward value that can be used in a variety of training situations (e.g., praise supporting the maintenance of obedience to command) and behavior-therapy contexts, but may be especially useful in the context of facilitating social attachment and confidence. The most significant source of reward for dogs that is obtained in the context of electronic training is mediated by the successful control of the aversive event. Perceiving that the e-stimulus is controllable by purposive efforts is not only a profound source of reward mediated by enhanced comfort and safety, but such learning contributes to the integration of an adaptive coping style via the organization of control-expectancy modules (prediction-control expectancies, calibrated establishing operations, and specific actions or sequences). When an aversive event is successfully terminated, reduced, postponed, or avoided in accordance with a rule or set of prediction-control expectancies, the dog acquires an increased sense of confidence or power over the threatening event. Repeated successful control over aversive events promotes competence, confidence, and a high-power control style conducive to elation, contentment, and well-being.

With the dog orienting toward the trainer, it is induced to come with affectionate encouragement and rewarded in ways conducive to promoting a sense of safety. If the dog attempts to turn away from the trainer instead, the LLES is applied and sustained until the dog turns back again. Once more, as the dog turns its head, S^{r-} (voice, click, or tone) is delivered just before stimulation is discontinued. After brief intertrial delays, similar trials are repeated until the dog rapidly turns its attention toward the trainer as soon as the e-stimulus is delivered. This escape phase of training is followed by an avoidance phase in which the dog's name is spoken just before the smooching or squeaker sound is made to intensify the orienting response. If the dog fails to orient, the e-stimulus is applied at a slightly higher level and immediately removed just as the dog turns toward the trainer. If the dog responds to its name alone, the reward bridge ("Good') is delivered just as it turns toward the trainer.

Recall Enhancement

Recall enhancement is easily integrated with attention-control training by saying "Come" just as the dog steps in the direction of the trainer. On every occasion in which the dog successfully comes, it should be enthusiastically praised, rewarded, and released following the various procedures described in Chapter 1. Compelling a dog to come via ES is usually unnecessary and should be avoided unless special circumstances warrant such training. In some cases, prompting (repeated momentary pulsing) with LLES may be necessary to compel a highly resistant dog to come; however, most dogs learn to come reliably with positive reinforcement alone, especially after electronic training is used to enhance attention and impulse control. During the early phases of recall and attention-control training, there is a strong tendency for inexperienced trainers to point or poke the handheld transmitter at the dog as they deliver stimulation. This is not necessary and may actually cause the dog to become overly aware of the trainer as the source of stimulation and adversely affect its response to electronic training. The dog does not need to know where the stimulation is originating in order for it to be effective. As a general rule, it is best not to move or show the dog the transmitter. This precaution helps to minimize the risk that the dog might associate the movement of the hand with the e-stimulus. This is especially critical in situations where the trainer is in full view of the dog. Stimulation should prompt the dog to seek security by making contact or by cooperating with the trainer's instruction. Throughout the electronic training process, the trainer's role is that of constructive guide and source of support and security. As a

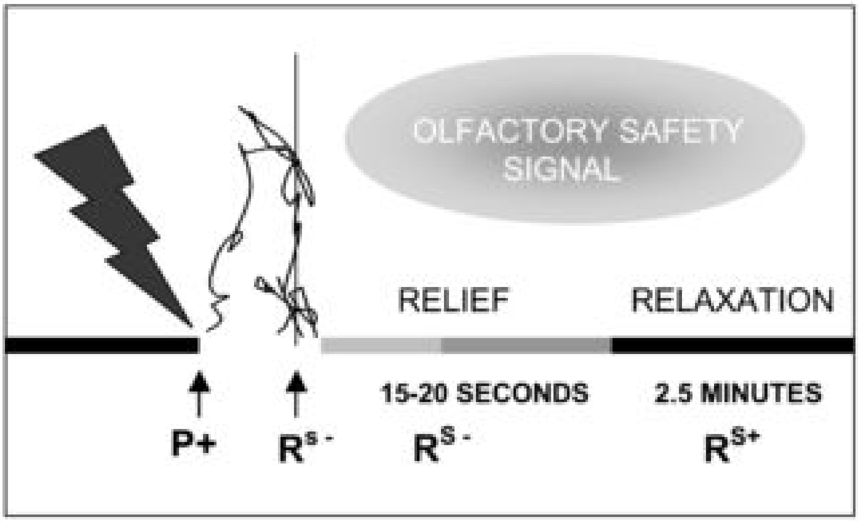

FIG. 9.1 The conditioned negative reinforcer R^{s-} immediately precedes the termination of the e-stimulus (P+), followed by opponent relief and relaxation (safety), providing both positive (R^{S+}) and negative (R^{S-})reinforcing effects. An olfactory stimulus presented to overlap with the postevent opponent relief and relaxation effects may gradually acquire conditioned associations capable of producing feelings of safety.

result, properly employed electrical training may significantly enhance a dog's connection and willingness to cooperate with the trainer.

Enhancing the Freeze Response

Training a dog to freeze on command dramatically enhances impulse control and recall reliability. The following procedure assumes that the dog has received long-line training as discussed in Chapter 1 and has been exposed to preliminary recall enhancement with LLES. With the dog on a long line and bolting toward some distraction, the command "Stay" is spoken in an abrupt and assertive tone just in advance of a brief pulse of high-end MLES. As the dog stops, the trainer quickly moves to the dog's position or calls it to "Come," whereupon the response is appropriately reinforced with sustained petting and food. An intertrial period of 2 1/2 to 3 minutes is provided to give the dog time to benefit fully from the ensuing postaversive relief and relaxation response. During this relief/relaxation period, various reward-based training and play activities are used to enhance the dog's confidence in the trainer as a source of safety and nurturance. The foregoing procedure is repeated under increasingly difficult and distracting circumstances until the dog learns reliably to freeze in response to the "Stay" command without ES. With each level of mastery, the dog is trained to freeze, stay, and to come when called. Recall is highly prepared under such circumstances, with the dog seeking the safety of close contact with the trainer. After the dog comes to a halt, its name is called. If the dog turns, a reward bridge is presented (e.g., "Good" or click), and the dog is called to "Come." As the dog reaches the trainer, it is appropriately rewarded with appetitive-positive and social-positive reinforcement. If the dog fails to orient (as may occur under the influence of a strongly distracting stimulus), a whistle or squeaker is presented and, if necessary, LLES is delivered together with directive prompting with the a long line. If the dog begins to come, but then turns away toward the distraction, a stronger level of LLES is delivered to secure control and turn the dog's attention away from the distraction. In cases involving dogs with particularly strong motivational interests in some activity or object in the

environment, higher levels of aversive ES may be needed to counteract the attraction. In general, establishing strong impulse control by conditioning a reliable freeze response is a necessary preliminary to obtaining a consistent and reliable recall sequence. After exposure to the stronger e-stimulus used in freeze training, a dog's response to LLES may undergo sensitization, perhaps allowing the trainer to use even lower levels of ES in the future.

Wait and Back

A useful way to enhance impulse control is to apply brief low-level stimulation during the wait and back exercises at the door when leaving the house for a walk. Preliminary training of the wait exercise teaches the dog to respond to the opening of the door by backing away ("Back") and waiting ("Wait") to be released ("Okay"). If the dog lunges ahead before being released, LLES is applied and repeatedly pulsed until the dog backs away from the doorway. The dog quickly learns that it can control stimulation and escape or avoid it by backing away or waiting in response to the door opening or by responding to the vocal signals "Back" and "Wait." Training a dog to wait and to back away from the door is a useful preliminary to enhancing slack-leash and controlled-walking behavior.

Walking on a Slack Leash

Excessive pulling on leash is a common complaint of dog owners. Although pulling can be controlled with traditional methods or halter restraint, such methods for some owners may be impractical or unsuccessful. Conventional halter training is particularly problematic because, when the halter is removed and the dog walked on a flat or slip collar, the pulling behavior may immediately recover despite conscientious positive reinforcement of more acceptable walking behavior while on the halter. Dogs exhibiting persistent habits of lunging or bolting at people, vehicles, or other animals show a pronounced and lasting benefit from even a very brief exposure to electronic training while on leash. The simplest approach is to directly link the presentation of low stimulation at the earliest moment in the pulling sequence and discontinue stimulation at the instant the dog backs off the leash. Surprisingly, most dogs with only modest preliminary training can learn not to pull, requiring only a few low-level stimulations (barely perceptible or imperceptible to human touch). Another method that is highly compatible with slack-leash techniques (see Chapter 1) is to pair momentary stimulation at a higher level with the spring release of slack or just after saying "Easy." An alternative method involves turning away from the pulling dog and applying stimulation just as the leash slack is dropped. By responding in a timely way to these cues, the dog can avoid ES. Once the dog is walking without pulling, appropriate rewards are used to strengthen more focused slack-lease walking, including periodic quick-sit/stay and instant-down/stay exercises.

Enhancing Emergency Exercises: Quick-sit and Instant-down

In the context of problem solving, electronic training is sometimes used to enhance emergency exercises that a dog has already learned (e.g., quick-sit, instant-down, and stay) through positive-reinforcement procedures. Also, in some situations, it may be necessary to improve the speed or reliability of the quick-sit or instant-down, especially when a high degree of impulse control is needed to maintain control in the presence of disruptive environmental distractions or adverse motivational arousal. Using ES to enhance behavioral control assumes as a starting point that the dog possesses a working understanding of the response being strengthened. For example, in the case of the quick-sit, the dog should demonstrate a viable sit response acquired through positive reinforcement and directive training. Again, the basic procedure is carried out with the e-collar set at the lowest level needed to evoke an orienting response and mild annoyance but without causing evidence of startle or discomfort. During the escape phase, ES is presented just before delivery of hand and vocal signals,

which provide the dog with previously acquired information that it can use to escape, that is, control the e-stimulus. Just as the dog begins to sit, the S^{r-} is presented and LLES is immediately discontinued, followed by vocal encouragement and the delivery of various other rewards as the dog completes the action. This procedure is repeated until the dog responds without hesitation and rapidly sits, indicating that it has learned that sitting turns off ES. If the dog has trouble sitting in the presence of ES, the response is induced by appropriate leash prompting or physical manipulation. The avoidance phase is a critical step in which the dog learns that hand and vocal signals can be used to avoid turning on ES in the first place, while setting the occasion for the subsequent delivery of positive reinforcement. During the avoidance phase, the dog's name is spoken to obtain its attention just before the command "Sit" is given in a normal tone followed by the hand signal—a delayed prompt. As the dog sits, appropriate positive reinforcement is delivered; however, if the dog fails to sit, the e-stimulus is applied together with leash prompting and physical manipulation sufficient to induce the dog to sit. If the dog successfully avoids the e-stimulus by sitting in response to the vocal and hand signals alone, the reward bridge ("Good" or click) is presented, followed by positive reinforcement. At the conclusion of each exercise or sequence of exercises, the dog is released with an "Okay" and hand clap.

In addition to strengthening the sit response with negative reinforcement, electrical training can be effectively used to enhance sit-stay reliability. This is a significant shift in emphasis. Instead of strengthening an active response through escape-to-safety training, the goal is to inhibit some action, improve impulse control, and increase the duration of the selected response. The stay exercise is carried out at both the sit-front position and the starting position at the trainer's side, as well as practiced under various naturalistic situations. Electrical stimulation should be delivered together with the command "Stay" at the earliest sign of movement indicating an intention to break the sit-stay position. If necessary, the dog is prompted by leash or physically guided back into the sit position. An important aspect of effective stay training is to emphasize the duration of the response and the release. In fact, in an important sense, stay behavior is most effectively trained by conceiving it as a antecedent waiting period or contingency in anticipation of a response leading to reward. As such, the release signal "Okay" or the opportunity to perform some other response is integrated with the stay behavior. The release from the stay contingency is explicitly trained with reward, just as any other control module. In basic training, control modules (e.g., sit, down, and stand) are treated as default stay exercises; that is, the dog should learn to remain in the position until it is explicitly released with an "Okay" or another command. Gradually, the dog is exposed to progressively more distracting and difficult situations until the quick-sit and stay response is reliable and steady.

Training dogs to drop instantly on command and to stay there is a very useful exercise for highly active, impulsive, and otherwise difficult-to-control dogs. Although the vast majority of dogs can learn to perform the necessary sequence of behaviors without the use of electronic techniques, some highly intrusive, impulsive, and oppositional dogs may resist conventional training efforts. Such dogs often rapidly benefit from electronic enhancement training of the emergency instant-down and stay response. The instant-down is particularly useful for owner's who lack sufficient physical strength or motor ability to otherwise control such dogs. Preliminary training should include intensive reward-based conditioning and shaping efforts and conventional inhibitory training. In advance of electronic enhancement, the dog should exhibit a well-developed understanding of the instant-down and down-stay behavior. Electrical enhancement of the down response is carried out with the dog in both the sit and the stand positions, with the trainer stepping on a slack leash as LLES is delivered, followed by the appropriate vocal and hand signal. If the dog fails to lie down, momentary pulsing of LLES together with appropriate leash prompting or physical assistance should be applied. Once the dog learns to escape the e-

stimulus by quickly lying down, the vocal and hand prompts are given before stimulation. If the dog responds appropriately, the reward bridge is presented at the moment in which the dog begins to lie down, followed by petting, food, and other rewards as the response is completed. Evidence of strong resistance to lying down in the presence of ES usually indicates that additional preliminary reward-based training is needed. The instant-down and stay exercise is practiced in a way similar to the procedure described for the quick-sit and stay. If the dog attempts to get up, ES, coupled with necessary leash prompting, is delivered at the earliest signs of movement and continued until the dog lies back down, whereupon ES is immediately discontinued and followed by appropriate bridging and positive reinforcement. At the conclusion of the instant-down and stay exercise, the dog is released with "Okay" and a hand clap. As with the quick-sit and stay, the instant-down and stay is practiced under varying conditions, lengths of time, distances, and distractions, thereby improving its usefulness and reliability for emergency control purposes.

Behavioral Equilibrium

Any highly motivational training technique may produce behavioral imbalances. As a result, certain classes of highly reinforced behavior may gradually dominate a dog's repertoire to such an extent that the expression of other behavior may be significantly impeded or blocked. For example, in reward-based training, a dog may tend to stay excessively close to its trainer in an effort to maximize its chances of getting food, gradually making it more difficult to shape exercises that either require it to move away from the trainer or to stay away at some distance. Other reinforcement-related imbalances may take the form of anticipatory behavior. For example, dogs that have been repeatedly called after a brief sit-stay may learn to anticipate the recall signal and come without waiting as required. In this case, the recall response is stronger than the stay response, reflecting an imbalance of readiness to perform the one response at the expense of the other. Simply returning to the dog occasionally and rewarding it for staying can help to offset the anticipatory imbalance and restore equilibrium (see Tortora, 1983).

Electronic devices are frequently used to discourage undesirable behavior via punishment. As a result, the dog gradually learns to regard the e-stimulus as an inhibitory signal, causing it to freeze when the collar is activated. This would be a highly undesirable outcome if one wished to negatively reinforce a behavior requiring the dog to move toward or away from the trainer. Ideally, the dog should learn to increasingly respond to ES as an e-signal anticipating safety and reward rather than an aversive event compelling escape. Other problems may emerge if the device is used exclusively to reinforce a fixed sequence of exercises negatively, such as sit and down, always sequencing them in the same order. Numerous other potential imbalances may emerge during training, some beneficial and others detrimental to training objectives. The single most important consideration to keep in mind to avoid problematic imbalances is to engender in the dog a confident attitude with respect to its ability to predict and control significant events, whether attractive or aversive. Dogs that habitually fail to exercise control over significant outcomes, particularly aversive ones, may develop a pattern of inflexible and ritualistic behaviors to cope with difficult situations. Even though such rituals are ineffective as means to control attractive and aversive events, they may serve to reduce distressing arousal (e.g., escalating anxiety and frustration) associated with behavioral incompetence. Behaviorally incompetent and insecure dogs tend to prefer familiar activities that minimize the risk of failure, even though they produce a low rate of reinforcement, whereas competent and confident dogs are more willing to engage in risk-taking activities and experimentation (actions with uncertain outcomes) to produce an optimal range and quantity of reward and safety. Perhaps the best general strategy to ensure beneficial balance is to encourage the dog to engage in behavioral experimentation that involves a balance of both attractive and aversive events arranged to occur with sufficient difficulty to increase the dog's functional competence and confidence.

Punishment and Aversive Counterconditioning

Radio-controlled e-collars are commonly used to punish (suppress) unwanted behavior. Since the intent of punishment is to produce rapid and complete suppression of the target behavior, the process typically involves significantly higher levels of stimulation than used to shape behavior with negative reinforcement. As a result, the levels of ES used for punishment purposes pose significantly more risks and potential problems than those associated with LLES. The more aversive the stimulation, the more accurate and precise the stimulation needs to be in order to avoid problems. Consequently, HLES is typically delivered in the form of a brief pulses lasting a fraction of second. Only e-collars incorporating a momentary function that prevents overexposure to HLES should be used to deliver such stimulation.

In contrast to LLES, HLES is prone to produce a number of undesirable side effects that require a great deal of care and expertise to prevent or manage. HLES can produce significant pain, fear, and distress, aversive arousal that may persist in some dogs by becoming associatively linked with the context or neutral stimuli present during inappropriate or lengthy HLES. Instead of promoting escape/avoidance behavior with negative reinforcement, HLES risks indiscriminately producing fear of the place or things present at the moment of stimulation, causing the dog to acquire a lasting aversion toward them, even though they might be entirely irrelevant to the actual cause of stimulation. Further, rather than learning to emit behavior instrumental to escape or avoid the stimulation, the dog may simply learn to be afraid of it. The intense emotional arousal elicited by HLES may impede efficient learning or evoke undesirable reactive behavior, even aggression, in some predisposed dogs. Fearful or aggressive behaviors immediately preceding the cessation of aversive stimulation may undergo significant negative reinforcement. Consequently, a major concern associated with punitive procedures is the risk of generating and reinforcing highly undesirable behavior in place of the target behavior being punished. For example, punishing a dog with HLES when it jumps up on guests may cause it to avoid entering the foyer or, perhaps, depending on the dog's temperament and propensity for such behavior, elicit intense fear or aggression toward the visitor at the moment in which stimulation is delivered. Dogs that succeed in running through an electrical boundary may inadvertently learn to avoid ES by running through the field in the future. Such dogs may subsequently run through the boundary as quickly as possible when threatened by the warning tone rather than simply backing away from it.

Aversive counterconditioning is most often used to counter or offset the appeal of intrinsically reinforcing activities. These techniques are most often used to control activities or appetites that might threaten dogs with injury or death. The intent of such training is to instill a lasting aversion toward some object or place. For example, many dogs are fascinated and beguiled by the sound made by rattlesnakes. By applying an intense ES as the dog approaches a rattling snake, it learns, often after a single trial, to avoid such sounds and creatures. In aversive counterconditioning, an attractive stimulus is paired with a strongly aversive one. The goal is to reduce the appetitive value of the stimulus for the dog. Punishment, on the other hand, is primarily focused on reducing the frequency or strength of some instrumental behavior. A common problem involves dogs that persistently chase cars or bicyclists. Because cars and bikes are common things, causing a dog to become overly fearful and avoidant toward such things would not be desirable. Instead, the goal is to suppress the chase response itself by means of aversive stimulation. Successful suppression appears to combine both behavioral avoidance and object-place aversion, with the associated object-place serving as a discriminative stimulus signaling avoidance.

Electronic Training and Problem Solving

Electronic collars have been recommended and shown effective for the rapid suppression of numerous behavior problems, including

chasing after a variety of objects and other animals, territorial aggression, excessive barking, stealing and destroying household items, pica, coprophagia, aggressive-intent (lunging) behavior toward other dogs, compulsive behaviors (e.g., tail chasing), fence jumping and other boundary-escape behaviors, and refractory mouthing and biting in puppies (Polsky, 1994). Hart and Hart (1985) have described e-collars as an effective way to remotely punish misbehavior in dogs. Aside from the advantage of remote application, e-collars enable trainers to deliver a highly controlled stimulus, at variable intensities, with a degree of accuracy and consistency that is not available by any other means.

Electrical Stimulation and Excessive Barking

Although many authorities deem the use of bark-activated collars inappropriate for controlling nuisance barking at separation, such devices appear to exert a significant suppressive effect over separation-related barking behavior. In addition to producing a sharp reduction of barking at separation, many owners and trainers have noted a significant calming effect associated with the use of such collars. A survey of dog owners that used e-collars found that many owners noted that their dogs were calmer and "more settled" after its use. Those owners that used a bark-activated collar noted universally a calming effect (Coleman and Murray, 2000). A disturbing finding detected by this survey was that among the 30 respondents, only one dog was regularly permitted in the house. Aside from suggesting that excessive barking and roaming problems may be causally related to rigid exclusion of the dog from the household, it emphasizes the importance of preliminary behavioral counseling that focuses on quality-of-life causes that might underlie the etiology of such problems. Without identifying and modifying such contributing causes, reliance on punitive measures (electronic or otherwise) is a highly problematic and ill-advised strategy of behavior control. Beaudet (2001) has suggested that the use of bark-activated spray collars is an effective adjunct to control territorial and protective barking as well as barking associated with separation anxiety, fear, or compulsive etiologies. This is a somewhat unexpected benefit, especially if one considers separation distress to be an anxiety-based problem. Given such an emotional etiology, one would predict that startle should exacerbate the problem barking—not reduce it. How can this apparent paradox be resolved? First, obviously, not all separation-related barking is exclusively caused by anxiety, and this could account for many instances of improved behavior (see *Separation Distress and Coactive Influences* in Volume 2, Chapter 4). But, even in cases of separation distress where anxiety clearly appears to play a role, a significant number of dogs appear to improve rapidly after exposure to electronic training when an electrical or spray stimulus is used. In the case of ES, a plausible way to interpret these observations is in terms of relief/relaxation and emotional opponent processing that ensue after shock is terminated. According to opponent-process theory, aversive stimulation evokes slave affects of opposite hedonic valence (Solomon and Corbit, 1974). After repeated exposure to aversive stimulation, the slave or b-processes become progressively robust, pronounced, and sustained (see *Opponent-process Theory and Separation Distress* in Volume 2, Chapter 4). These opponent b-processes include the confluent evocation of relief and relaxation. Denny (1971), who has thoroughly studied this phenomenon in the laboratory (see *Safety Signal Hypothesis* in Volume 1, Chapter 8), has found that relief rapidly displaces fear shortly after the termination of shock and continues to build in strength for 10 to 15 seconds into the post-shock period. This relief response is primarily autonomic in nature and gradually followed by a more generalized relaxation response. Paradoxically, so long as aversive stimulation is brief, escapable, and spaced in time, the net result predicted by opponent-process theory and the safety-signal hypothesis is progressive relaxation—not increased anxiety. In the case of separation-related barking, added beneficial effects may accrue as the dog learns to avoid

stimulation by not barking. Theoretically, each time the impulse to bark is inhibited, thereby avoiding stimulation, the dog may experience repeated and deepening episodes of relief, relaxation, and enhanced confidence. If this theoretical assessment is accurate, the overall emotional effect of such training is progressively to generate a very significant internal counterconditioning influence, perhaps of sufficient magnitude to offset anxious arousal during periods of separation. Additional benefits could be obtained by presenting a continuous olfactory safety signal timed to coincide with the onset of relief following ES and continuing for 3 minutes, thereby overlapping both the relief and the relaxation stages of the opponent process. A bark-activated collar could be designed and programmed to perform this task. In addition, the collar could periodically deliver the odorant in small, nonstartling amounts at variable times so long as barking has been absent during the period immediately preceding the odor's presentation. The use of an intermittent olfactory safety signal would serve to calm and reassure the dog while simultaneously reinforcing quiet behavior.

Whether one chooses to use a bark-activated spray collar or an e-collar, such devices must be used with great care with dogs exhibiting separation distress with coactive anxiety or panic symptoms. Bark-activated collars work because they produce a strong inhibitory effect over barking, but, in some dogs, instead of calming them as previously suggested, such devices may evoke increased excitability, distress, or even global panic. One illustrative case involves a female Brittany spaniel that was 11 years old when her owner moved into an exclusive high-rise condominium and had gone back to work after a long hiatus between jobs. The dog's reaction to this change in routine was to bark continuously and to eliminate whenever the owner left her alone. According to the owner, both of these problems arose only after the change in home and routine. The dog's incessant barking led to a flurry of nasty complaints by her new neighbors. The owner consulted a veterinarian (her brother) who recommended that she use a crate and a bark-activated e-collar. Rather absentmindedly, she put the collar on the dog and left her alone in the crate for the day. She later confessed that she had rushed out of the apartment to avoid hearing the dog yelp when the collar went off. When the owner returned home, she discovered to her horror that the dog had broken out of the crate. The dog's efforts to escape from the crate had resulted in severe lacerations of her feet and caused her to break off several teeth. The dog was covered in urine, feces, and blood—materials that were tracked and smeared into carpets and furniture. This is a rather exceptional case, but it does underscore the potential dangers involved when using crates or antibark devices to control separation problems. Such tools should be recommended with great care and their use avoided in the case of highly unstable and reactive dogs.

Electrical Stimulation and Refractory Compulsive Behavior

Refractory compulsive behaviors are a source of considerable distress for many dogs and owners. In addition to evidencing psychological stress, such problems often result in physical injuries to dogs. Compulsive habits may persist despite intensive behavior-modification efforts, prompting the use of various means of physical restraint and medical interventions involving psychotropic drugs. Excessive self-directed licking may result in acral lick dermatitis (ALD) (see *Excessive Licking* in Chapter 5), which is often associated with dermal hyperplasia and ulcerated lesions developing on affected areas, especially the carpus and tarsus joints. ALD may resist treatment efforts unless the dog's licking activity can be prevented. Prevention measures often include the use of Elizabethan-type collars, bandages, or various repellents applied to the affected area. Some of the treatments may cause the dog significant discomfort (e.g., glucocorticoids injected directly into the lesion) and require repeated administration. Although various pharmacological agents (e.g., clomipramine and fluoxetine) may significantly attenuate the habit, the benefits of such medications to control excessive licking depend on the sus-

tained use of the drugs, with the unwanted behavior often recurring when the medication is discontinued. Not only are the long-term side effects of prolonged psychotropic medication unknown in dogs, such medications are relatively expensive and may represent a significant strain on the household budget of many dog owners.

Eckstein and Hart (1996) performed a study to evaluate the use of radio-controlled ES to suppress excessive licking associated with ALD. The five dogs selected for the study were equipped with an e-collar (Tri-Tronics), providing the delivery of three momentary stimulations (3.3, 13.2, and 59.0 msec). Owners were instructed to use the minimum duration of stimulation needed to interrupt licking behavior. For all dogs, the medium duration (13.2 msec) was sufficient to inhibit licking. Initially, the owner delivered the stimulation while hidden from the dog's view, but, as the training progressed, ES was delivered in different contexts, including at times when the dog was in the owner's presence. Between training sessions, dogs were required to wear Elizabethan collars, at least until licking had been absent or rare for 6 hours or more. On average, licking was suppressed in four of the five dogs after a mean of 11.8 electrical events delivered over 12 to 50 days. The suppressive effect of the protocol was highly durable, and relapse was quickly resolved with a brief period of remedial training. The variable length of time required to obtain full suppression may have been due to differences in the amount of time owners devoted to the training program.

Considering the extremely rapid and lasting benefits derived from a dozen or so brief pulses of momentary ES, the procedure described by Eckstein and Hart would seem to represent an important advance in the humane treatment of such problems. A significant advantage of the procedure is its simplicity—a factor that recommends its use by average dog owners. Interestingly, though, Hewson and Luescher (1996) have criticized the method as being too difficult for the average owner to follow because "the technique was used according to a particular protocol, something most owners cannot do" (156). Oddly, they then go on to recommend an arguably more complicated protocol requiring that the owner train the dog to perform some response that is incompatible with licking. When licking occurs, the owner is instructed to distract (startle) the dog from the activity by blowing on a duck call or shrill whistle, whereupon it is cued to perform the incompatible response. This general procedure is repeated every time the dog licks during the 6-week treatment program. In addition, the authors recommend that the owner never "rebuke or punish" the dog since such treatment might worsen the problem, but offer no concrete evidence supporting their rationale or data demonstrating the effectiveness of their treatment protocol. Eckstein and Hart preemptively respond to potential "humane" criticisms, writing,

> The use of electronic shock collars may be questioned by some animal handlers; however, compared with the discomfort of intralesional injections, prolonged use of Elizabethan collar, or both, a limited number of momentary shocks should be considered a humane alternative. (1996:226)

Employing ES in the treatment of ALD should include a preliminary veterinary examination and appropriate treatment of any active lesions. The trainer should attempt to identify and remove sources of behavioral stress adversely impacting the compulsive habit. The long-term benefit of electrical conditioning for the control of ALD is enhanced by the incorporation of various enrichment and training programs. In addition to daily exercise and social activities involving play and compliance training, various counterconditioning efforts involving the use of food and massage should be employed. If an e-collar is selected to help control excessive licking, the dog should be first properly introduced to it in the context of safety training. *Safety training* involves a strategy designed to enhance a dog's control over aversive events while simultaneously exploiting the inherent relief/relaxation effects associated with the successful escape and avoidance learning. The dog learns that ES is controllable and safe by the trainer introducing it at low levels—those just suffi-

cient to reinforce previously conditioned orienting and basic obedience exercises (e.g., sit and stay). Such preliminary training helps to reduce the risk of inducing undesirable fear or stress in association with aversive training.

Using ES to train a dog not to lick should consist of three phases: escape, avoidance, and reinforcement of an alternative behavior. During the escape phase, LLES is applied to interrupt licking. The moment the dog stops licking, a conditioned negative reinforcer (e.g., "Good" or click) is presented and the e-stimulus is immediately turned off and the vocal signal "Relax" is delivered. The avoidance phase of training involves the presentation of a vocal avoidance signal (e.g., "Stop") just before the e-stimulus is activated. By responding immediately to the avoidance signal, the dog can avoid the presentation of the e-stimulus. With the cessation of licking, the dog is tossed a treat or toy, thereby further reinforcing the response and providing the dog an alternative outlet for oral activity.

Once the dog learns that it can escape or avoid the e-stimulus, a more aversive event can be introduced with the goal of further suppressing the compulsive ritual. Now, if the dog fails to respond immediately to the avoidance cue "Stop," a momentary stimulus consisting of a stronger intensity is delivered, depending on the dog's sensitivity to ES. During this phase of training, a dilute odor and repellent taste can be applied sparingly to the area with a cotton squab, thereby providing an additional reminder not to lick the area. As the result of aversive ES, significant emotional relief typically follows within 3 to 5 seconds, with opponent relaxation building after another 2 to 3 minutes. During the relaxation phase, a safety odor (e.g., citrus scent or dilute lavender) can be presented together with a toy and reassuring affection. The idea is to associate the odor with relaxation while redirecting the licking activity away from the dog's body toward a toy. This procedure is repeated as necessary. The e-stimulus involved need not be too intense, but it should be strong enough to suppress the licking behavior rapidly (see Eckstein and Hart, 1996). Although the initial sensitizing exposure should be moderately strong, subsequent stimulations can be milder, with the voice reprimand "Stop" often being sufficient. For optimal effectiveness, the e-stimulus should be paired with the earliest intentional movements anticipating a licking episode. A radio-controlled spray device (with or without odorant) might also be useful for such purposes. To guard against excessive contextualization, the dog should be observed in various situations and ES appropriately applied, as needed. Finally, it is particularly important to observe and apply ES with the owner both in and out of the dog's view. A remote wireless camera can be very effective for such purposes. Between sessions, the dog should wear an Elizabethan collar until it is evident that the licking compulsion has abated. In all cases, daily basic training should be performed together with exercise, play, massage, and other quality-of-life enhancements, as appropriate. In addition to providing an effective alternative for refractory ALD, electrical training is a viable adjunctive treatment procedure for the control of a variety of other compulsive habits requiring immediate interruption and precise timing of aversive stimulation (e.g., tail chasing and whirling).

Electrical Stimulation and Aggression

The value of electronic training for the control of aggressive behavior has been known for many years, but procedures incorporating ES remain a lightning rod for controversy. A common and erroneous allegation suggests that ES elicits aggression in dogs or makes aggressive dogs more aggressive. While it is certainly possible that exposure to a highly aversive and uncontrollable e-stimulus may elicit aggressive panic and phantom snapping in some reactive dogs, ES delivered in measured and controllable doses can be effectively used to enhance behavioral control in dogs prone to show aggression in response to direct control or restraint techniques. LLES has been recommended as an adjunct to other behavior-therapy efforts for the control of noncompliant behavior associated with dominance aggression (Borchelt and Voith, 1996). Of course, ES is used only for dogs not likely to escalate aggression in response to such

stimulation. ES can be particularly useful in the treatment of location- and object-guarding behavior, providing a highly effective way to compel the dog to relinquish control over some location or object while channeling incompatible safety-seeking behavior toward the trainer. The power of ES to control aggression is probably the result of the dog learning that compliance and cooperation are more effective than aggressive threats and biting as a means of controlling such events. The net result is twofold: (1) a rapid disconfirmation of established prediction-control expectancies and establishing operations mediating aggressive threats and attacks, and (2) the establishment and subsequent confirmation of alternative prediction-control expectancies and establishing operations that promote social behavior incompatible with aggression.

When properly introduced and applied, ES does not typically cause dogs to escalate aggressive behavior, but generally exerts an opposite inhibitory effect. If delivered well in advance of the flash point of no return (see *Proactive versus Preemptive Processing and Cynopraxis* in Chapter 8), the most common effect of contingent ES is to trigger behavioral inhibition and deescalate aggressive arousal. In the context of a comprehensive cynopraxic therapy program, most dogs showing mild to moderate aggression problems appear to become increasingly pacified, relaxed, and cooperative as the result of exposure to radio-controlled training, provided that the preliminary reward-based training and enhancement procedures, as described previously, are carried out by a competent and skilled cynopraxic trainer. In particular, radio-controlled ES or vibrotactile stimulation can be highly effective for the control of intraspecific aggression—especially aggression between dogs sharing the same household. When brief LLES/MLES or vibratory stimulation is applied in a timely manner, such that an incipient threat sequence or juncture responsive to de-escalation is overlapped by the contingent presentation and cessation of ES, the stimulated dog usually shows a pattern of phasic inhibition and attenuation of aggressive arousal, followed by a heightened responsiveness to vocal command and trainer control efforts. In the context of escalating interdog tensions, ES may cause the provocative dog to emit postural and intentional changes that the target dog may interpret as signifying cutoff or submission, causing both dogs to adopt a motivational shift incompatible with fighting. Many target dogs exhibit an unsettled appearance after observing the unexpected and rapid shift in intent and behavior shown by the stimulated provocator, and appear to be surprised and concerned about the unknown cause of the change. In addition to helping to defuse aggressive tensions between the dogs, the motivational shift (establishing operation) evoked at such times is conducive to the integration of alternative behavior previously acquired in the context of reward-based training. Finally, radio-controlled ES enables a trainer to manage proxemic distances and dynamics between potential adversaries while minimizing the risk of producing adverse interference effects that might otherwise occur as the result of direct interactive control efforts.

Undoubtedly, aversive stimulation can cause certain dogs exhibiting a reactive coping style to respond with fear and escape behavior or even to show autoprotective aggression, especially when escape is barred and the stimulation is perceived as otherwise uncontrollable or extraordinary in terms of threat magnitude. However, under structured and controllable circumstances, ES may also be used to temporarily attenuate or even permanently suppress aggression in dogs (Tortora, 1983). When confronted with an aversive social event, a dog is prone to exhibit a combination of two general coping patterns or *styles*, depending on the severity of the event and the degree of control it perceives to have over the event. Threatening aversive events perceived as lacking controllability tend to preferentially activate the flight-fight system (FFS) and prompt reactive adjustments, whereas safe aversive events perceived as predictable and controllable tend to facilitate adjustments in accord with acquired prediction-control expectancies and calibrated establishing operations, thereby promoting competent and confident adjustments. In safe

aversive events, the positive hedonic processing and rewards associated with repeated escape to safety appears to antagonize and countercondition elicited fear stimulated by the event, thereby gradually reducing reactive escape-from-fear adjustments. That aversive events exert variable effects on dogs is consistent with the presence of individual temperament differences and differentiating learning experiences affecting the way dogs cope with and perceive aversive social challenges and threats. Whereas social challenges and threats perceived as such may invigorate aggressive behavior in dogs operating in accord with a reactive coping style, social challenges and threats perceived as safe and controllable tend to promote adjustments conducive to appeasement and reconciliation.

Obviously, significant conflict is apt to occur if the trainer is viewed by the dog as both the source of aversive stimulation and the provider of guidance and safety. Consequently, efficient safety training depends on the dog not linking the e-stimulus with the trainer. When stimulated, the dog should learn to look to the trainer for help while learning to escape and avoid the e-stimulus. In an important sense, the trainer should be perceived as a source of safe guidance to the dog, providing commands, hand signals, conditioned reinforcers, and leash prompts while helping the dog to escape and avoid the aversive event while learning to obtain safety and the comfort of various other rewards controlled by the trainer (e.g., play, massage, petting, and food). Consequently, in addition to reducing aggressive behavior and promoting prosocial behavior, radio-controlled training may enhance attachment dynamics and communication between the trainer and the dog. Finally, insofar as the dog perceives the trainer as a source of safety (relief and relaxation), the trainer may also acquire potent and lasting reward properties (see *Electrical Stimulation and Harm to the Handler-Dog Bond*).

Many types of canine aggression have been described and categorized according to the eliciting situation or motivational states presumed to mediate the threat of attack (see *A Nomenclature of Aggressive Behavior* in Volume 2, Chapter 6). Tortora (1983) has subsumed several common types of aggressive behavior under the functional category of avoidance learning, suggesting that aggression is often learned as a means to control aversive social situations (see *Avoidance Learning and Aggression* in Volume 2, Chapter 6). According to Tortora's hypothesis, aggression toward people is learned via escape/avoidance (negative reinforcement) conditioning involving stressful or threatening situations. By training a dog to escape or avoid aversive or threatening stimulation with cooperative behavior, avoidance-motivated aggression is gradually replaced with a repertoire of behaviors that are incompatible with reactive opposition and aggression. Learning to successfully escape or avoid aversive stimulation promotes the development of expectancies of safety, further enhancing the dog's ability to cope with adverse social interaction in a more confident and prosocial way.

To achieve this change, Tortora devised a controversial program for rehabilitating aggressive dogs. The protocol focused on training dogs to perform 15 basic obedience exercises (AKC-CDX). The initial training process involved object and interactive play and force training. Training progressed from a continuous schedule of reinforcement, where every correct response was rewarded with play, to an intermittent schedule [variable ratio (VR) 5 and, eventually, VR 15]. Once the 15 exercises selected were under basic control, training with ES commenced. During the training process, the selected exercises were shaped through progressive stages to meet demanding performance criteria. In addition to training on the kennel grounds, the dogs were conditioned to respond reliably under a variety of circumstances:

Sidewalks with pedestrians and traffic
Busy shopping malls
A local shelter with many barking dogs
Household-type environments
A classroom with 20 to 60 students

Escape training was initiated with LLES just sufficient to get the dog's attention but not eliciting fearful behavior. The level of ES was progressively increased during training, until the dogs could tolerate and perform

under HLES. As the dogs emitted the appropriate escape response, a safety signal consisting of a tone was immediately presented as the e-stimulus was turned off. The arrangement was designed to establish a conditioned association between the tone and poststimulation relief and relaxation. Poststimulation relief and relaxation serve to positively reinforce escape/avoidance behavior, as well as evoke a state of emotional arousal incompatible with fear. Conditioned stimuli repeatedly paired with the onset of relief and relaxation can gradually acquire the ability independently to elicit similar states of arousal and be employed to countercondition fear. Denny (1983), commenting on Tortora's study, summarized the significance of relief and relaxation in the process of safety training:

> Relief is conceived of as a short latency, autonomic event that lasts only 15 to 20 sec. Relaxation, on the other hand, seems to be a long latency, striate muscle event that requires at least a 2.5-min nonshock period to be effective. Both relaxation and relief are assumed to be effective in making the stimuli associated with a nonshock period positive, or safe, during the acquisition of avoidance and in providing the responses that can compete with fear and help mediate its extinction. According the theory, both relief and relaxation occur automatically with the extended removed of an aversive or well-conditioned aversive stimulus. Nothing else is required. (215)

In addition to establishing a safety signal, a warning vibrotactile buzz (conditioned avoidance stimulus) was presented just after the command. The dogs learned that they could escape ES by quickly performing the required obedience response or what Tortora refers to as an *operand*. With the emission of the target response, the safety signal was delivered for 2 seconds. An avoidance procedure brought the obedience response under the stimulus control of a command. By responding in a timely and correct manner, a dog could avoid ES and produce the positive reinforcement via the safety signal and play. During the avoidance-training phase, progressive improvement was observed in the dogs' performance, even though ES was no longer delivered. Gradually, both the safety tone and periods of play were placed on an intermittent schedule. As dogs reached this point in the training process, they were exposed to various stress and distraction tests designed to maximize the generalization and transfer of safety training. Dogs were tested for aggressive propensity "under maximally stressful and aggression-inducing circumstances, for example, while the animal was roughly handled and beaten about the body with a rolled-up newspaper or switch" (1983:188). During this phase of testing, failure to comply with obedience commands or the display of aggressive behavior was followed by the delivery of HLES (full intensity). This final stage or *normalization* also involved phasing out the e-collar and transferring the trained behavior to the dog's home environment.

Tortora treated 36 dogs with the foregoing protocol. The reported results are very impressive, with all treated dogs showing a "complete and permanent" cessation of aggressive behavior. Tortora observed a number of other benefits directly attributed to safety training:

> Produces highly durable and reliable compliance responding
> Reduces fear and other stress reactions
> Promotes an appearance of enhanced confidence in the dog

Tortora's work appears to reveal several significant factors in the acquisition and control of aggression in dogs, but the treatment program is rather extreme and may benefit from various refinements and modifications. The general protocol may be made more effective and usable by minimizing aversive stimulation while maximizing the use of positive reinforcement, play, and safety conditioning. The use of full-intensity HLES and other procedures involving provocative and aversive handling of dogs raises significant welfare concerns. Tortora does not demonstrate the necessity of such highly aversive and potentially traumatic experiences for effective safety training. Further, dogs selected for the study were exposed to the same general procedures irrespective of temperament and individual sensitivity differences. The treatment protocol was identical for different dog breeds exhibit-

ing varying behavioral propensities (Saint Bernard, German shepherd, chow chow, Dalmatian, standard poodle, springer spaniel, and Kerry blue terrier, among others). Also, positive reinforcement was limited to the safety signal and an opportunity to play—an activity that is not equally rewarding for all dogs, especially those with a history of aggression. The schedule of intermittent positive reinforcement used to maintain the repertoire of obedience responses was extremely lean—probably unnecessarily so. Perhaps significant benefit and minimization of aversive stimulation could be achieved by presenting food and other rewards on a more dense frequency of reinforcement that incorporates positive prediction error.

Another potential improvement in the protocol would be the use of an olfactory safety signal in combination with or in place of an auditory one. In contrast to the 2-second safety tone paired with relief following the termination of aversive stimulation, an olfactory stimulus (e.g., dilute lavender or chamomile) can form an association with the more sluggishly recruited relaxation responses, as well. In addition, the incorporation of vocal praise and encouragement with petting and massage would provide another form of constructive safe stimulation to pair with relief, perhaps helping to enhance relaxation and establishing more positive associations with human contact. An advantage of conditioning voice and tactile stimuli as safety signals is the ease with which they can be generalized and transferred to everyday activities in a dog's home environment. The benefit of pairing a sustained olfactory stimulus or set of social stimuli with both relief and relaxation may be significant for the maximization of the benefits of safety training and the promotion of trust between the dog and the trainer. Denny (1983) notes, in his comments regarding Tortora's report, that conditioned safety effects are doubled when the safety stimulus is paired with both relief and relaxation. Given the central significance of the safety signal in the safety-training protocol outlined previously, it is odd that the e-collar is gradually faded out and eventually removed from a dog altogether as part of the final normalization phase of training. Removing the collar from the dog appears highly problematic, because the delivery of the safety signal depends on the collar to deliver the requisite conditioned tone. This loss of signaling capability seems inconsistent with the repeated emphasis and importance placed on the safety signal for reducing fear and aggression and its value as a source of positive reinforcement for compliant behavior. In contrast, olfactory, vocal, and tactile conditioned safety signals would avoid such difficulties, perhaps enhancing the process of generalization and transfer, as well. Despite the apparent effectiveness of safety training for the treatment of aggression in dogs, the protocol has attracted little interest and, to my knowledge, has not been experimentally replicated, although safety training using ES offers many potentially beneficial applications in canine behavior therapy.

Electrical Stimulation and Chasing Behavior

Another common application of ES in dog training is the control of chasing and predatory behavior. The radio-controlled and behavior-activated delivery of ES has been proven effective for suppressing predatory behavior in dogs, coyotes, and wolves (see *Electronic Training and Wildlife Conservation*). For example, Andelt and colleagues (1999) at the National Wildlife Research Center's Predator Research Facility (Logan, Utah) found that HLES rapidly suppressed coyote predatory behavior toward lambs. Even when ES was delivered during attack, the researchers reported immediate suppression and no evidence of escalation or increased aggressiveness. In Norway, Christiansen and colleagues (2001a) evaluated the use of remote electronic training for suppressing canine predatory behavior toward sheep. The study period was 2 years and involved 114 dogs, consisting of three breeds: Norwegian elkhounds (35), English setters (56), and hare-hunting dogs (23). The dogs were administered a 1-second pulse of ES when they approached within 1 to 2 meters of sheep confined to a pen. The researchers found that a lasting suppression of predatory

behavior was produced by the protocol (Christiansen et al., 2001b). After a year, only one dog that received ES training continued to attack sheep. The effect showed significant generalization to ordinary circumstances, with approximately 75% of the owners of trained dogs reporting that their dogs no longer showed an interest in sheep. Similarly, Stichnoth (2002) has demonstrated that the chase and hunting behavior of beagles can be rapidly suppressed with the aid of radio-controlled ES, without producing evidence of cardiovascular distress or physiological stress. As an adjunct to reward-based training efforts, radio-controlled ES can also be used to rapidly and effectively suppress the chasing of cats and other animals by dogs. Despite ample evidence that ES works effectively to control chasing and predatory behavior, organizations such as the Companion Animal Behavior Therapy Study Group (CABTSG) continue to suggest otherwise, but without offering any substantive research to backup their emotional convictions and charges of harm and ineffectiveness (CABTSG, 2003). In addition, they suggest that other methods are currently available that have been proven to provide better control and management of such problems, but fail to identify a method or offer a single citation referring to the powerful methods of control in question. Instead, they vent an emotionally charged diatribe of speculation that is largely contradicted by the prior research previously discussed.

Several advantages are derived from the radio-controlled application of aversive stimulation for the control of behavior problems associated with chasing behavior: It provides an exact level of stimulation, can be precisely timed and delivered at a distance, and helps to generalize training to situations in which the owner is absent. With a proper foundation of positive training in place, radio-controlled electrical or spray (e.g., citronella spray) stimulation offers a highly effective means to inhibit the territorial chase response in resistant dogs. Although electronic training can effectively deter persistent chasing behavior in dogs, the use of spray stimulation or ES should be considered only after a careful assessment and preliminary training have been carried out. Once preliminary training has been performed, electronic training can help to enhance the reliability of inhibitory control.

Initially, the dog is exposed to recall training on a long line, with electronic training introduced only after the dog attains 90% reliability. The dog should be trained to orient to its name and halt forward movement in response to the command "Stay" spoken assertively. The orienting response can be effectively conditioned with LLES, whereas the inhibitory halt response may require a higher level of momentary stimulation to reach reliability. Electronic training should be combined with a conditioned stimulus (e.g., whistle or throw rings). By blowing a whistle or tossing a set of throw rings close to the dog immediately before and contiguous with the electrical event, a strong inhibitory association can be rapidly established. After pairing the throw rings with the e-stimulus, the jingling sound will produce a strong inhibitory response, providing an effective means to generalize a conditioned suppressive effect. Prior to every ES event, the throw rings are flipped once in the hand. The rings should be thrown only if the dog ignores the warning and requires remote stimulation. The throw rings need not strike the dog, but should bounce near enough to produce an impression. During the early stages of electronic training, the dog should be kept on a long line to ensure that the appropriate response is given during ES and to prevent unanticipated problems.

Electronic Training and Wildlife Conservation

In addition to select dog-training and behavior-therapy applications, electronic training devices may play a significant future role in the management of wildlife, particularly tracking and deterrence systems used to protect endangered species or livestock from predation. Several studies have used radio-controlled or behavior-activated collar systems for predator control. For example, conservationists working in California found that foxes living on San Clemente Island preyed on nestling loggerhead shrikes (*Lanius ludovi-*

cianus mearnsi), a severely endangered bird species living on the island. Wildlife biologists affiliated with the Institute for Wildlife Studies (2000) employed an ordinary electronic dog-containment system to deter fox predation on shrike nestlings. Whenever the collar-equipped foxes came too close to the shrike nests, an electrical shock was delivered, thereby protecting the nestling shrikes from harm and training the foxes to avoid the nests. The technique of electrical deterrence was studied as an alternative to lethal control that would have been otherwise necessary to protect the shrikes from further decimation.

A similar effort to develop a predator-deterrence system has been launched by the U.S. Fish and Wildlife Service (USFWS) and U.S. Department of Agriculture (USDA) Wildlife Services, with the cooperation and support of the University of Montana and prominent wildlife conservationist groups. The objective of the study, under the scientific direction of John Shivik (USDA Wildlife Services), is to explore the efficacy of aversive electrical conditioning to control undesirable predation by wolves. Wolves that prey on domestic animals are often killed when other means of control fail. Four wolves suspected of repeated attacks on cattle were captured north of Gardner, Montana. The controversial experiment consisted of fitting the three surviving wolves (one of them, an adult female, died while in captivity) with containment dog-training collars and penning them with a calf fitted with an approach-activated transmitter. When wolves wearing radio-controlled collars approached the calf too closely, a brief tone stimulus was followed by the delivery of an ES producing "discomfort but not pain" (Bangs, 2000c). Successful deterrence has been reported with coyotes fitted with e-collars. Attack-contingent ES quickly conditioned coyotes to avoid attacking lambs that were placed in their pens (Andelt et al., 1999). Treated coyotes were exposed to the highest level of stimulation produced by the Tri-Tronics Model 100 Lite (325 pulses/second of 600 to 640 V at about 32 mA). The coyotes rapidly acquired a lasting avoidance of sheep that continued for several months after treatment without intervening electrical reinforcement.

Besides investigating the efficacy of aversive control on livestock predation, the researchers hope to learn whether treated wolves will desist from predation on cattle once the wolves are released into the wild and transmit the aversion as a tradition to other wolves subsequently raised by the pack. According to Bangs, the Wolf Recovery Coordinator for the USFWS, researchers in the former USSR (Republic of Georgia) successfully conditioned wolves with dog collars to avoid livestock when released from captivity. In addition, future generations of wolves learned through cultural transmission from the behavior of conditioned wolves to avoid livestock as prey animals. Research with dogs has not produced very promising results in this regard (Christiansen et al., 2001c). Sheep-chasing dogs paired with sheep-avoidant dogs (previously exposed to ES) showed an initial reduction in chase incentive but over time exhibited an increasing tendency to chase and attack sheep independently.

In the ongoing wolf experiment, preliminary results suggest that wolves may rapidly acquire an aversion toward calves as the result of approach-activated ES (Bangs, 2000a). One wolf that approached a calf hide with a transmitter placed on it was apparently stimulated, because it jumped back from the hide and avoided contact with it in the future. Other pack members watching the stimulated wolf's reaction seemed to have also acquired an avoidance response by observation. None of the three wolves subsequently approached the calf hide after the frightening incident. Further, avoidance behavior toward the calf hide appears to have generalized to live calves, at least temporarily. Calves were repeatedly left alone with the wolves, with one young calf spending a night in the wolf pen without evidence of molestation. It remains uncertain whether the avoidance is the result of predatory inhibition resulting from nervousness associated with close confinement or the result of the single (known) exposure to ES. Whatever the cause, the inhibition was not permanent, since the wolf that had been previously stimulated did finally attack a calf. Unfortunately, the collar either malfunctioned or the electrodes failed to reach the skin

through the wolf's thick fur. Subsequently, the collar was repositioned for better contact with the skin, evidently correcting the problem, since a November update (Bangs, 2000b) noted that the calf now could follow or chase the wolves around the pen, having apparently learned to use the power afforded by its collar transmitter.

The use of conventional containment-type collars for predator deterrence is thwarted by significant design and operational problems. The long-term use of collars delivering ES through metal electrodes making direct contact with the skin is prone to produce skin irritations, gradually resulting in necrotic lesions and infection. Another problem with such devices is the need to change or recharge batteries periodically—a problem that might be solved by incorporating a miniature solar-recharging system integrated into the strap of the collar. The problems associated with the electrode-skin interface might be addressed by a high-voltage collar with the ability to arc through the fur barrier or by an e-collar equipped with electrodes that are only momentarily brought into close contact with the skin through a servomechanism activated at the time of stimulation.

Electrical Stimulation and Working Dogs: A Shocking Study

Electrical stimulation is frequently used in the context of training working dogs, aiding the trainer in establishing reliable control over highly motivated and potentially dangerous behavior. Schilder and Van der Borg (2004) have published a report of disturbing findings regarding the short-term and long-term effects of shock used in the context of training working dogs that is destined to become a source of significant controversy. The authors arrived at their conclusions after observing several training sessions and analyzing video records of Dutch handlers preparing dogs for IPO [Internationale Prüfungs Ordnung (International Examination Rules)] certification. The authors report that they observed 32 dogs receiving 106 shocks delivered by a radio-controlled collar. In addition, they combined the results of comparisons between 31 German shepherd dogs divided into shocked and nonshock groups, with 16 dogs (14 males and 2 females) receiving shock and 15 (12 males and 3 females) not receiving shock during training. The main differences observed between dogs receiving ES and those receiving other forms of correction included an altered ear posture detected during obedience work and free walking, tongue flicking (appeasement licking) during protection work, and submissive pawing actions during obedience work.

Electrical Stimulation and Harm to the Handler-Dog Bond

According to the authors, even brief and infrequent shocks may be perceived as traumatic by dogs, causing them emotional harm and permanent social fear. The notion that Dutch working dogs might have become fearful of their handlers as the result of shocks received in training is reported as an obvious fact that is never actually tested, leaving it to the reader to accept the speculation "as fact" or not. In practice, dogs do not appear to link ES with the handler, especially persons with whom the dog is closely attached and familiar. In fact, the most interesting uses of the collar depend on this lack of aversive association, including lasting reward and opponent safety effects (Denny, 1991). Interestingly, the IPO system has devised a good behavioral test for detecting mishandling and abuse. Surely, if an IPO dog had developed a fear or aversion toward its handler as the result of electrical training, the following IPO Watchdog Test [WH (Wachhunde Certificate)] requirement would likely reveal it, causing a great many dogs to fail if they were treated as badly as alleged by the present report:

> Devotion to the Handler (10 pts)
>
> The dog is put on lead and handed over to a second person. The handler then proceeds toward a group of people who are standing about 80 paces away. The dog is allowed to watch the departure of his handler until the handler has gone about 30 paces of the distance. At this point, the dog is taken behind a

> wall or similar structure so that his handler is no longer visible to him.
>
> When the handler arrives at the group, he walks into the center of the group and stops. While he is in the group, the handler may not make himself noticeable to the dog across from him. The dog is released from the lead by the second person. The behavior of the dog, especially the use of the nose, is to be observed during this exercise. When the dog has found his handler, he is to be praised. (Frawley, 2003)

If the electrical and physical stimulation during protection work were truly traumatic and stressful, one would expect that the traumatized dog might be apt to flee at the first instant it got a chance. Further, one would expect that its willingness to bite and hold the sleeve ought to decrease in proportion to the amount of fear and pain it experienced (e.g., causing the dog to come off the sleeve too early or not to bite as hard) or that the dog might even show signs of avoidance and fear toward the agitator. However, no such loss of drive or performance is reported. In fact, Dutch dogs are renowned for their hardness, work enthusiasm, and acrobatic attacks—attributes that are opposite to what one would expect from training that was overly stressful. With increased biological stress, as in sickness, one would expect to observe a drive-reducing effect on aggression and a loss of voluntary initiative, whereas increased fear should tend to suppress behavior rather than enhance it. The absence of reduced drive or behavioral suppression with respect to critical activities associated with shock (e.g., bite work) makes one skeptical about the lasting adverse effects that the authors claim to document. Although they offer no substantive evidence of trauma or harm to the dogs, they provide loads of speculation, anecdotes, insinuations of gender and educational inadequacies, and derogatory comments regarding the motivation and competence of IPO trainers in its place.

Most scientific evidence supports the notion that the cessation of aversive ES in the context of escape/avoidance training is more likely to enhance social attraction, promote feelings of safety, and calm a dog rather than make a dog afraid or apprehensive. These secondary effects of shock termination and pain reduction have long been recognized to promote conditioned and unconditioned effects conducive to reward and safety (see *Electrical Stimulation Controllability and Safety*). Instead of instilling social aversion and anxiety as suggested by the authors, competent electronic training may actually promote social attachment, reward, and safety. With the behavior-contingent cessation or avoidance of ES, dogs experience immediate emotional relief that subsequently merges into a state of progressive relaxation incompatible with social aversion and fear—a sequence of opponent emotional effects contrary to those alleged to occur in the case of working dogs exposed to ES in the context of training.

The opponent effects of relief and relaxation on social behavior are exemplified in a series of controversial experiments that used shock to promote desirable social behavior in profoundly autistic children. Lovaas and colleagues (1965) at the University of California, Los Angeles, used ES and its contingent termination to facilitate the expression of increased approach and affectionate behavior based on the following hypothesis:

> Any stimulus which is associated with or discriminative of pain reduction acquires *positive* reinforcing (rewarding) properties, i.e., an organism will work to "obtain" stimuli which have been associated with pain reduction. The action of such stimuli is analogous to that of stimuli whose positive reinforcing properties derive from primary positive reinforcers. (99)

The first of these experiments involved placing a child with pervasive emotional and social deficits between two experimenters who faced each other from a distance of 3 feet. Whomever the child faced encouraged him to approach closer with outstretched and gesticulating arms, saying "Come on" as a painful electrical current was delivered to the child's bare feet via strips of metal tape applied to the floor. If the child hesitated longer than 3 seconds, he was pushed forward into the beckoning arms of the "saving" experimenter by the other "helping" experimenter located behind the child. As the child moved in the direction of the experimenter, the shock stimulus was immediately terminated. In addition to rewarding social behavior via an escape to

safety, the shock stimulus was contingently applied to suppress tantrums and self-stimulatory behavior. According to the authors, the experiment was highly successful, with the children (identical 5-year-old twins) subsequently exhibiting improved alertness, increased social approach behavior, and more affectionate behavior to the experimenters—changes that lasted for 9 months without any additional aversive stimulation. The boys also exhibited a significant decrease in tantrum and self-stimulatory behavior stemming from the contingent application of shock, and this changed behavior continued for 11 months without additional training. In another experiment involving these same twins, a radio-controlled stimulator (Lee-Lectronic Trainer) was fastened to a belt and situated so that the electrodes made contact with the child's buttocks. Affectionate social contact (kissing and hugging) was encouraged by the experimenter, who faced the child and bowed in his direction, saying "Kiss me" or "Hug me." If the child, who was held fast at the waist, failed to kiss the experimenter or hug him, a medium-level shock was delivered via radio control. As the result of the foregoing procedure, the boys were rapidly trained to kiss or hug the experimenter on cue. In a third study again with these same twins, the researchers evaluated the effects of shock reduction and safety in terms of acquired reward properties associated with the experimenter. As the result of an association established between the experimenter, pain reduction, and successful escape to safety, the presence of the experimenter became a significant source of reward for the children, as quantified by lever-pressing behavior whereby the children were given brief contact with the experimenter contingent upon performance of the lever-pressing task. The authors conclude with the following remarks regarding the apparent beneficial effects of contingent shock escape/avoidance and pain reduction:

> It seems likely that the most therapeutic use of shock will not lie primarily in the suppression of specific responses or the shaping of behavior through escape-avoidance training. Rather, it would seem more efficient to use shock reduction as a way of establishing social reinforcers, i.e., as a way of making adults meaningful in the sense of becoming rewarding to the child … Once social stimuli acquire reinforcing properties, one of the basic conditions for the acquisition of social behaviors has been met. (108)

These theoretical and experimental findings have been repeatedly validated in the context of formal obedience training, where dogs initially showing profound social inhibitions and fears become increasingly affectionate, confident, flexible, interactive, and playful in association with directive training (see *Electrical Stimulation Controllability and Safety*). Despite a significant amount of aversive stimulation used in the context of traditional dog training, dogs exposed to such training typically acquire a heightened level of affection toward the trainer, who is usually treated as a social reward object. The petting and praise that are strongly emphasized in such systems of training mediate significant reward, perhaps as the result of a similar paradoxical effect in response to pain reduction and the successful escape/avoidance (safety) of aversive collar stimulation and physical force, paralleling the findings of Lovaas and colleagues.

Fisher (1955) exposed several groups of puppies to different rearing conditions consisting of variable amounts of environmental enrichment, social contact, punishment, isolation, and control over aversive events. From around week 3 to week 15, one group of puppies [enriched (E)] were given 30 minutes of daily exposure to various sources of environmental and social stimulation, receiving consistent friendly handling by the experimenter, and were never punished. Another group of puppies [ambivalent (A)] were given 30 minutes of similarly permissive and playful environmental and social stimulation followed by 30 minutes of repeated punishment, consisting primarily of manhandling and hitting with a switch. During the punishment period, whenever a puppy attempted to approach the experimenter or another puppy, it was punished. The puppy was also punished if it explored the test area or played in the experimenter's presence. When receiving physical punishment, the puppy could flee to the safety of a hiding place but was often removed from there and punished more. Elec-

tric shock (via a 50-V dry-cell battery regulated by potentiometer) was used to punish social approach behavior within a small inescapable compartment. The shock punishment was delivered to the puppies' feet under two conditions: (1) whenever two puppies approached each other within the compartment and (2) after a puppy approached an experimenter coaxing it from outside the compartment. Two other groups were kept isolated, except that one group of isolates [punished (P)] was also treated roughly and exposed to the daily punishment treatment as group A; the other group of isolates remained in their cages until final testing. During subsequent testing at weeks 12 and 13, four of the six puppies exposed to the pattern of indulgence and punishment appeared to view the experimenter as an enhanced source of reward and security, spending significantly more time in close proximity with the experimenter than did indulged puppies. However, two of the puppies exposed to the combined indulgence and punishment treatment showed a strong avoidance of the experimenter indicative of aversion, suggesting that individual differences of a genetic origin may affect the way dogs respond to such treatment (see Freedman, 1958). Interestingly, the indulged-punished group showed a significant reduction in general activity and exploratory behavior and reacted more intensely toward extraneous noises and movements than did the consistently indulged group, perhaps indicative of a lowered startle threshold toward novelty. As such, aversive procedures used in the training of working dogs may promote strong one-person bonds and facilitate a desire to please via an acquired perception of the trainer as enhanced source of social reward and an increased alertness and reactivity for novelty and change consistent with the necessary preemptive readiness and social wariness of working dogs toward strangers.

Ambiguous Social Behavior: A Sign of Stress or an Enhanced Readiness to Submit and Obey?

Instead of instilling social aversion and anxiety as suggested by the authors, the foregoing animal and human research supports the notion that competent electronic training appears to promote positive social attachment, safety, and reward effects that may be provided and amplified via affectionate petting and reassuring praise. The preponderance of scientific evidence suggests that ES escape/avoidance and pain reduction should promote long-term effects that are incompatible with fear and stress, making the trainer an object of significant extrinsic reward that actually enhances the dog's welfare via an improved capacity for social coping, learning, and adaptation. Evidently, many of the shocks delivered by the handlers were far from traumatic experiences for the dogs, since the authors had to double-check with them to confirm the actual number of shocks received by the dogs. The following passage makes clear that the handlers probably used shock in a measured and contingent way that provided the dogs with significant behavioral control:

> The durations of most reactions to shocks were immeasurably short, possibly due to the fact that dogs were asked to obey some command or take some action immediately afterwards. (321)

From the foregoing description, it appears that ES was applied in a manner that met controllability standards, further making the attribution of stress and welfare harm resulting from electronic training seem more like an unfounded accusation than a scientific conclusion. Assuming that the handlers used both momentary and continuous levels of stimulation, the evidence also suggests that the dogs did not respond to longer durations of shock as being particularly painful; that is, the initial "immeasurably" brief reactions appear to indicate startle, a psychological response, but not reactive sequelae indicative of traumatic pain. In any case, for most dogs, the apparent enjoyment derived from the protection-training process itself far exceeds the periodic penalties that occur while learning how to play the "attack game" in accord with appropriate rules. Furthermore, once critical limits and fair-play rules are set via inhibitory conditioning (e.g., all-stop, stop-change, and go/no go), the social and play rewards associ-

ated with the activity itself should exert potent counterconditioning effects, thereby further reducing any secondary aversive emotional conditioning effects arising from inhibitory conditioning with shock. These various bits of circumstantial evidence conflict with the allegations that shock, as used by IPO trainers, promotes social fear, stress, and represents a serious threat of harm to the long-term welfare of trained dogs.

The ambiguous social behaviors that the authors represent as markers of fear and stress have been previously investigated and interpreted differently elsewhere (Beera et al., 1998). In that work, distinctions are drawn between behavioral indicators of fear, stress, and submission evoked by a moderately strong shock in comparison to other sources of startling stimulation. The researchers found that a robust cortisol release was produced by nonsocial fear-eliciting stimuli (e.g., electrical shock and blast of a nautical horn), however, provocative handling and startle (e.g., repeated physical restraint and opening an umbrella) in a social context produced negligible cortisol secretion. Significantly with respect to the behavioral correlations of the present study, they learned that nonsocial aversive stimulation, such as shock, produced a relative absence of oral behaviors (e.g., lip licking and tongue flicking). These previous findings suggest that activation of the HPA system occurs predominantly in response to nonsocial aversive events, whereas aversive stimulation occurring in a social context tends to produce precursor submission behaviors (intention movements) with a relative absence of concomitant biological stress. These findings are consistent with a motivational partition between stressful fear elicited by nonsocial aversive stimuli and submission behaviors evoked by social challenges and threats (startle), perhaps via a modulating effect of person. Whereas the increased oral behaviors and postural changes shown by laboratory dogs were previously interpreted as signifying an increased readiness to submit, these same behaviors now, as exhibited by working dogs toward their handlers, are characterized in an entirely different light, with the present authors now arguing that such oral behaviors and changes in posture and gesture implicate fear and aversion toward the handler as the result of receiving shock in the handler's presence.

A substantial body of prior research has also shown that the critical factor affecting adverse stress and welfare parameters is the relative control that the dog has over the delivery of appetitive and aversive events. Despite this prior work regarding the important linkage established between event uncontrollability and stress, no effort was made by the authors of the present report to sort out the effects of controllable versus uncontrollable ES. Nevertheless, the dogs in the present study appear to adequately learn to control the electrical event, and since there is no significant evidence reported that suggests that the dogs suffered a loss of biological fitness or physical or mental harm due to ES, there is little justification for the use of the term "stress" to describe the present findings, especially so since prior evidence shows that contingent and controllable ES delivered by a radio-controlled collar in the context of dog training produces negligible immediate or lasting biological stress per cardiovascular and HPA-axis markers (Stichnoth, 2002).

If one defines *welfare* as "The state of an individual as regards its attempts to cope with its environment" (Broom and Johnson, 1993:1978), one might even argue that contingent ES probably exerts a long-term beneficial influence on the dog's welfare insofar as it enhances its efforts to acquire an adaptive coping style. Finally, if the behavioral differences attributed to shock in the handler's presence are interpreted in a manner consistent with the observations of Beerda and colleagues (1998), one arrives at an entirely different set of implications. Instead of indicating the presence of stress and fear, the slight lowering of posture, oral behaviors, and increased paw lifting are now viewed as precursor submission behaviors expressed in the context of coping successfully with an aversive social event. Consequently, if one accepts the behavioral changes described by the authors at face value, all that one might fairly conclude is that ES, in the context of obedience and bite work, generally establishes effective

inhibitory control over target behaviors (e.g., bite release) while enhancing the dog's readiness to defer to handler command and control, as indicated by the presence of increased precursor submission behaviors.

In conclusion, contingent ES at the levels normally used in competent dog training is not intrinsically stressful or a threat to a dog's welfare and may be highly beneficial to the extent that it promotes adaptive behavioral change and improved coping skills (see *Stress, Distress, and Potential Adverse Side Effects of Electrical Stimulation*).

Is Physical Traumatization and Manhandling Really Better Than Shock?

The authors appear comfortable with the idea that "beatings and other harsh punishments, such as kicks or choke collar corrections" are somehow preferable to shock, since dogs exposed to such treatment do not show presumptive behavioral signs of stress and lasting fear that they claim occur from brief and contingent ES. Regardless of how one feels about the use of dogs for police and military work or dog training in general, implying that beating or kicking a dog is in some way preferable to brief ES is simply wrongheaded and makes no sense from a training or welfare perspective. Further, placing a slip-collar or prong-collar correction in the same category as beating or kicking a dog reflects a profound lack of knowledge and appreciation of the training process and how such devices are used to achieve training objectives. Many dog trainers on both sides of the e-collar controversy have struggled for decades to refine the training process into the humane and sophisticated art that it has become today, only to have it mandated that manhandling and brutalization are not a significant threat to a dog's welfare. There is no need for complicated statistics to demonstrate adequately that harshly striking a dog can exert potent and lasting adverse social and emotional effects that significantly impair its capacity to function and cope effectively, as amply demonstrated by Solomon and colleagues (1968). Abusive hitting and manhandling can also exert variable long-term developmental impairments of social behavior dependent on individual differences and rearing histories (Fisher, 1955; Freedman, 1958).

Construing that physical abuse might be less of a threat to the welfare of working dogs than is a brief dose of harmless ES is simply bewildering and impossible to take seriously. The notion that dogs might be better off getting choked, beaten, and kicked rather than receiving contingent ES makes absolutely no sense and is contradicted by common practical experience. In dog training, not only is the e-stimulus precisely defined in terms of duration and intensity, it can be delivered and stopped with precision, with very little generalization (if any) to the handler, producing minimal signs of discomfort or subsequent distress to the dog and no sign of physical trauma. ES has the added benefit of hundreds of experimental learning studies involving dogs and other species, providing a comprehensive knowledge base for its use as a training tool. In addition to the slip, prong, and halter collars, a wide range of electronic training devices are recognized by the *Professional Standards for Dog Trainers* (Delta Society, 2001) as effective and humane tools of the trade. Along with radio-controlled electrical and spray collars, bark-activated and containment devices are included in the standard and treated as professional equipment for the control and improvement of dog behavior.

Methodological Concerns and Recommendations

Methodological aspects of the present contribution to the dog welfare literature are disturbing and deserving of further attention. The first of these concerns is the woeful lack of appropriate controls to limit experimenter bias and assumptions concerning the use of aversives in dog training. Neither of the authors openly acknowledge a prejudice or bias for or against electronic training, but the authors clearly bring to the study some established negative beliefs about the subject matter, as evident in the first line of the introduction, where electronic training is lumped together with beatings and other means that cause "wounds, pain and mental harm" (320) to dogs. Later in the text, they also link

"choke collar corrections" with kicking, beating, and other "harsh punishments" (332), raising further concerns about the authors' knowledge and understanding of the dog-training process and the tools used by practical dog trainers. Schilder has previously urged that the *only* legitimate use of an e-collar is for suppressing predatory behavior (sheep killing) (*Applied Ethology Listserve*, September 20, 1996, 07:27:00.30), making the conclusions and recommendations of the present study appear somewhat like a foregone conclusion.

Despite the presence of obvious negative convictions toward dog training in general and electronic training in particular, the researchers took no measures to blind themselves to experimental and control groups, raising reasonable concerns about experimenter bias entering into the data collection process and post hoc treatments, which should necessarily be regarded as tainted and suspect. Further, the experimenters interacted with the trainers in ways that may have influenced them, thereby raising the possibility that a subtle element of participant bias had been introduced into the study. For example, to establish an accurate frequency of shock, they asked trainers how many times they had shocked their dogs. Aside from potentially making the handlers self-conscious about the number of shocks they delivered or, perhaps, causing them to increase or decrease the frequency of stimulation, such questioning may have caused some of them to deliver stronger levels of stimulation than might ordinarily be used in order to make the effects of shock more apparent to the observers. Several other potential participant bias effects might have easily slipped into the experiment as a consequence of handler interrogations regarding the frequency of the independent variable.

Although one might seriously doubt that any group of self-respecting trainers will ever again make themselves available for such a study, one possible way to perform blind and fair studies would be to have all the dogs wear an e-collar or a dummy collar. In addition, the experimenters might remain behind a blind while team assistants make video recordings of relevant training activities for later analysis. Once the training session is over, subsequent observations might then be made without the observers knowing which dogs were exposed to the independent variable. The experimenters manipulating and performing post hoc analyses of the collected data might only be permitted to see tapes and coded information in which the actual moment of stimulation is blocked from view, and an equal amount of video block is yoked to control dogs not receiving stimulation, thereby providing further precautions against bias. If a significant effect consistent with the hypothesis exists, the researchers should be able to identify it through observational and statistical means alone without knowing which dogs actually received the shocks. If correlations between particular behaviors and biological stress are of interest, in addition to observational data, relevant biological data should be collected at critical times before, during, and after the training session. In addition to obtaining salivary samples, temperature and real-time heart-rate measurements should be taken. By collecting various biological data before the e-collar is worn, while it is worn, and after it is removed, potentially significant within-subject effects might be identified and linked to associative learning resulting from ES. With a baseline of such relevant information, meaningful correlations between behavioral signs and biological stress might then be possible to establish. In the absence of biological markers, the attribution of significance to ambiguous or ambivalent behaviors presumed to index harmful stress struggles for footing at every step before collapsing, as it were, for lack of evidence.

Despite numerous variables affecting the quality, quantity, and subjective experience and potential harm of the e-stimulus, the authors make no effort to collect relevant data concerning the intensity or duration of the shock used by the handlers—variables that would significantly enrich the statistical analysis. The independent variable (ES) is treated as a constant of several thousand volts—a relatively meaningless open-circuit measure of electrical potential that is equivalent to the shock produced after scuffing one's feet on a carpet. In general, they treat shock as though any amount were bad, analogous to asserting

that the toxic effect of taking one capsule of phenobarbital is equivalent to taking a full bottle. They repeatedly emphasize that such devices produce stress, but provide no evidence that ES in the context of dog training overtaxes biobehavioral control systems or harms a dog's biological fitness in any way, making the use of the term "stress" seem unwarranted (Broom and Johnson, 1993). The data in the present study are derived from a mean of three shocks of an unknown duration and intensity. To extract the subtle causal relations that the authors attribute to ES from such limited exposure to a vaguely defined electrical event seems a daunting challenge further complicating the process of sorting out cause-and-effect relations between shock and the specific changes in behavior that are attributed to it. Given the demonstrated fortitude and resilience of dogs to hundreds of repeated shocks under laboratory conditions and protocols resembling torture (see *Stress, Traumatic Avoidance, and Laboratory Conditioning with Shock*), it is highly suspicious indeed that working dogs, bred for hardness and drive, would fall victim to lasting harm as the result of receiving three or so shocks during training. If true as reported, the real news in this study is not the effects of ES, but the constitutional weakness of Dutch working dogs. How dogs cope with ES and other forms of aversive stimulation is largely determined by individual differences of a genetic nature and the relative controllability of the events (Corson et al., 1973) (see *Electrical Stimulation Controllability and Safety*).

The authors suggest that a goal of their study was to determine the short-term and long-term effects of shocks, yet they fail to provide any data relevant to the determination of long-term effects. The short-term differences between the two groups in the present study were derived from averaged scores obtained by one-zero sampling at various times relative to some significant interactive event between the dog and handler (e.g., at 1 minute into free walking, they assessed tail, body, and ear positions; and, during obedience exercises, tail and ear positions were graded 3 seconds after the command; whereas other behaviors were graded 10 seconds after the command) and context. One might wonder what the results would have looked like if the sampling occurred after 2 minutes of free walking rather than 1 minute. Also, what would the results look like if a 3-second delay were used to sample target behaviors after the command in the aforementioned situations. For example, dogs stimulated 2 minutes prior to the observation window will likely show very different behavior from dogs stimulated 30 minutes prior to observation.

The small sample size, lack of controls for the effects of age (Beerda et al., 2000), interindividual differences and polymorphisms (Van der Berg et al., 2003), individual variations affecting stress proneness (see Vincent and Michell, 1996), and possible prior exposure to electrical training make the comparisons between shocked and nonshocked dogs statistically weak. Although the authors made some effort to match the shocked and nonshocked groups roughly in terms of breed and sex, controlling for the effects of age was completely neglected. This is not a minor point, because Beerda and colleagues (2000) had previously shown that socially ambiguous (nonspecific) displacement behaviors (e.g., increased licking) are strongly correlated with the dog's age. Despite an intimate familiarity with these earlier findings, the authors provide no information concerning the age of the dogs and apparently made no effort to control for this potentially significant source of error. The authors treat the presence of ambiguous social behaviors as an established behavioral index of stress, but, in fact, no such validated stress index exists.

The inventory of behaviors that the authors have identified in the present report as indicators of fear and stress have not been disambiguated under natural conditions, nor have they proven to be very reliable as markers of stress in the context of laboratory investigation. Ogburn and colleagues (1998) found that dogs wearing halters that clamp around the nose showed marked postural and behavioral differences (e.g., lowered head and ears back) indicative of fear and subordination in comparison to dogs wearing flat collars, who appeared more excited and difficult to control. Dogs restrained by halters also engaged

in significantly more biting at and fighting against the leash and exhibited a higher level of pawing. While wearing a halter, dogs appeared to avoid looking at the handler during obedience training, suggesting an adverse motivational effect on social engagement not present in the case of dogs wearing a strap collar. Despite these relatively robust postural and behavior changes indicative of distress, physiological testing for sympathetic arousal and markers of stress showed no significant difference between dogs wearing halters and dogs wearing flat collars. The tests performed included measurement of blood pressure and heart rate, respiration rates, and pupillary dilation, as well as ACTH and cortisol levels. These prior findings significantly conflict with the notion that such behaviors are markers of stress that represent a serious threat to a dog's welfare. Further, Beerda and colleagues (2000) have explicitly warned against the use nonspecific displacement behaviors for indexing stress. This previous work acknowledged a danger of misinterpretation when one draws conclusions regarding stress from the presence of ambiguous social behaviors, giving rise to a curious violation of the law of noncontradiction: "Because stress behavior is rather variable and often nonspecific to stress, it is readily misinterpreted" (60). The foregoing is a muddled proposition. A collection or set of behaviors cannot be logically classified as simultaneously belonging to and not belonging to the defining category or class. Insofar as *stress* is not functionally present in some instance of behavior, that particular instance is not an example of *stress behavior* but a behavior with functional characteristics exemplifying another class. The hypothetical set consisting of behaviors classified as *nonspecific* to stress with respect to the class of behaviors such that stress is a defining characteristic would necessarily be an empty one. Although a behavior may belong to more than one class or category, insofar as it possesses complex functional or descriptive characteristics appropriate to the inclusion and exclusion criteria of each classification (e.g., both offensive and defensive aggression are types of aggressive behavior), claiming that the behavior in question is nonspecific (that is, it simultaneously belongs and yet does not belong to one or the other category) would necessitate a third category (e.g., panic aggression). Finally, there are experimentally established ways for developing behavioral and physiological indices of stress, fear, and pain (see Broom and Johnson, 1993) that should be performed and rigorously validated before they are experimentally applied and used to justify a call for intrusive legislation. Traumatized puppies and dogs appear to show lowered startle thresholds and intensified startle responses, making tests evaluating prestimulation and poststimulation startle parameters a potentially useful index for evaluating the short-term effects of fear. Startle tests might also provide useful means for evaluating long-term fear effects in combination with physiological indicators of an impaired capacity to cope adaptively.

To increase the likelihood of extracting viable correlations from their data, the authors excluded behaviors that occurred in less than 50% of the dogs. While such a method might help to increase the likelihood of getting results, such post hoc manipulations also significantly reduce statistical power. Further, how can one be sure that this selection process is performed in evenhandedly? One obvious problem with the procedure is that certain traits that may have contributed to the selection of those dogs receiving electronic training might be confounded with the behavioral effects of ES. As a result, those common predisposing traits and behaviors exhibited by dogs receiving electronic training might be statistically amplified and mistakenly identified as representing between-group differences resulting from ES. For purposes of controlling these confounding variables, a baseline of within-subject data sets for the dogs receiving ES would need to be assembled prior to the exposure. A within-subject design (each dog serving as its own control) might help to avoid many of the aforementioned pitfalls. Such within-subject data collected for the experimental and control groups might be subsequently used to make more reliable between-subject comparisons between shocked and nonshocked dogs than allowed by the Schilder and Van der Borg design.

Alternatively, a larger sample might help to reduce some of the confounding effects resulting from individual differences and other uncontrolled sources of error.

The performance of multiple between-group comparisons in the absence of appropriate corrections for type 1 error is another troubling feature of the study. Type 1 error occurs when a statistically significant result is obtained due to chance. Repeated tests and comparisons can artificially cause the probability (*p*) value of some results to reach significance, just as flipping a coin enough times will eventually produce three heads in row. Consequently, to control the error rate associated with multiple comparisons, appropriate statistical precautions are taken, including the use of corrective procedures to avoid false positives. Without such corrections, there is a risk of turning up apparently significant results that do not actually exist. The more that statistical data are churned by multiple tests and comparisons, the greater is the risk that spurious results will be mistaken as significant differences. Despite an obvious potential for error favorable to their central hypothesis, the authors nevertheless rejected the need for a correction method because such treatment would likely cause much of what they held significant to vanish. The Bonferroni method was explicitly rejected, and the authors opted to publish their results in an uncorrected form to preserve the appearance of credible significance. Experimental findings that lack sufficient statistical strength to withstand appropriate corrections to prevent false positives are viewed with justifiable suspicion.

Implications

The authors grant that only small behavioral differences between the shocked and non-shocked dogs were found, yet they show little restraint or reserve in the way they interpret and amplify the significance of these slight differences with anecdotes and speculation. Even the title betrays a misleading implication with respect to the study's significance since the study design a priori lacks the capacity to make any meaningful determinations about the effects of shock received during training on the long-term welfare of dogs. Of course, the authors acknowledge that long-term harm cannot be extrapolated from their findings but then go on anyhow to assert that such significance nevertheless somehow does exist: "We have not proved that the long-term welfare of the shocked dogs is hampered, but we have made clear that it is under serious threat" (332). It is bewildering to consider how one might justify the claim that a causal relation exists, such that P gives rise to a serious threat of harm to Q, without first demonstrating that P can actually harm Q—otherwise the assertion that P represents a serious threat of harm to Q does not make any sense. On the other hand, though, if one already knows that P represents an increased risk of harm to Q, how can one state that a causal relation of harm between P and Q has not been established, such that given the occurrence of P then Q is threatened with future harm. Lastly, if, as established by the first part of the authors' foregoing statement, the long-term welfare of a dog after exposure to shock is regarded as undetermined, then P could just as easily have a long-term beneficial effect on Q or possibly exert no measurable effect at all with respect to harm or benefit to Q. Since a causal relation has not been established between an exposure to shock and long-term adverse effects, one can only conclude that biased assumptions and beliefs led the authors to the speculation that shock is stressful and represents a serious threat to a dog's welfare. Even allowing that brief shock might momentarily produce changes in behavior consistent with pain and fear, obviously a specter of *post hoc ergo propter hoc* ("after this therefore because of this") looms over the speculation that the transitory effects of ES might represent a serious threat to a dog's long-term welfare—speculation that has no legitimate place in a scientific work of this nature. Finally, in the absence of consistent operational (descriptive and functional) definitions of stress and welfare, applied impartially, these notions will rapidly degenerate into shifting (and therefore increasingly meaningless) concepts of convenience for

those wishing to impose their personal beliefs and preferences on others with respect to animal care and training.

Many of the negative statements and claims made by the authors conflict with prior evidence that they neglect to consider, stating that "no systematic investigations regarding possible long-term effects of the use of the collar have been published" (320). In fact, the available prior work provides behavioral and biological evidence that contradicts the allegation that contingent shock delivered by a radio-controlled collar is likely to promote long-term harm to a dog's welfare. Stichnoth (2002), for example, concluded, "If the dog is able to foresee and avoid the shock due to direct association with an object nearly no increase of salivary cortisol can be measured during the shock test and no increase four weeks later" (182). A similar lack of long-term adverse side effects has been reported in shock used to suppress predatory behavior (Christiansen et al., 2001a and b) and to control avoidance-motivated aggression (Tortora, 1982). Consequently, the authors of the present report have not proven that ES in the context of dog training poses a serious threat or any other harmful influence with respect to a dog's immediate or future fitness or adaptability (welfare). The assertion that shock used in the context of dog training poses a serious threat to a dog's welfare should be considered unfounded, at least until significant contrary evidence is made available.

Arndt and Bartko (2003) explore some of the ethical implications of intentionally failing to take appropriate measures to prevent false positives when performing behavioral studies involving multiple tests and comparisons:

> Since an underestimation of Type I error rates can lead to false impressions and treatment practices, this issue is of serious concern. While it may be comforting to speculate that follow-up studies will fail to replicate the spurious finding—hence eventually set the record straight—this attitude is becoming an increasingly shallow reassurance. All too often the popular press takes note of positive findings and reports them. Once the results are touted in the news, the public's knowledge about them is seldom corrected since follow-up negative studies are not deemed newsworthy. This not only is misleading it also unfavorably affects scientific credibility. Furthermore, the rapidity of information transfer effectively removes the "waiting period" safeguards that science once enjoyed. In times past, there was a slow, cautious progression from when scientific results appeared in journals to when the findings surfaced in popular practice. Given rapid publication, electronic publishing, and the Internet, this safeguard is vanishing.

The obvious dangers underscored by the foregoing passage are not without relevance to animal welfare research. Already in February 2003, results prefiguring the findings of the present study (published in March 2004) were presented before the British Parliament, representing the lone bit of scientific evidence given in support of banning the manufacture, sale, and use of electronic training collars in England:

> A Dutch study by Dr. Joanna Van Der Borg compared dogs trained using electric shock collars with dogs trained using more conventional methods. The shocked dogs showed persistent and long-term behaviour differences that indicated that they were under stress and in fear. (Rendel, 2003:column 870)

It is noteworthy that these claims attributed to the present study (or a related study not cited by the authors) include the assertion that "persistent and long-term behaviour differences" were found to result from the use of ES in dog training—a conclusion that might also be easily taken away from the study by uncritical readers. The danger should be obvious. An opinion, even an erroneous and unfounded one, cloaked under the authority of science carries great potential power to influence public opinion and policy-making decisions. Unfortunately, even after a flawed study is debunked, many diehards will continue to embrace and defend it, making it the meme of the day. Slowly by repetition and political pressure, such "snark bait" may even worm its way into the law, thereby violating the rights of everyone compelled to obey it.

Arbitrarily restricting the manufacture, sale, and use of e-collars or any other training tool recognized by the dog-training profession as standard equipment (see Delta Society, 2001) may violate federal antitrust laws that

guard against unfair infringements on free trade. In any case, such restrictions will not stop abusive behavior. Instead of making a beneficial change in the lives of Dutch working dogs, the most likely long-term consequence of the present effort to ban electronic training devices, should the efforts of Schilder and Van der Borg succeed, will be to increase the practical trainer's reliance on less efficient and potentially more harmful physical procedures, as needed to establish safe control over the working dogs' aggressive propensities and enthusiasm. Only education can hope to improve the way people interact with animals, but the power of education is based on the credibility and quality of the information provided and the integrity of the educator imparting it. Further, the arbitration of controversial welfare issues depends on a balance of science and ethics tempered by common sense and kindness. The key role of science in this process will only succeed to the extent that the scientist is recognized and trusted by all parties as a fair and objective arbiter, free of anthropomorphic emotionalism, private prejudice, malice, and legislative agendas. Legislation and policy changes that adversely impact established professional activities or infringe upon free trade are costly to society and represent a significant hardship to individuals and industries that are forced to bear the brunt of the burden. These sacrifices are part of social progress and human betterment, but they are costs that are onerous and hard to bear when the research used to achieve those ends is flawed. Every time a study published in a peer-reviewed journal contains unproven speculation that harms the interests of a particular group or product with misinformation, no matter how heartfelt the underlying sentiment, the whole scientific community will continue to suffer from the repercussions of mistrust long after the study is forgotten.

ELECTRONIC TRAINING COLLARS IN PERSPECTIVE

Although generally reliable, effective, and humane, electronic training aids have attracted considerable criticism in recent years. Much of the criticism is based on incomplete, biased, or faulty information about the nature of ES and the techniques used to deliver it. Many of the critics of electrical training are strikingly ignorant regarding the use and effect of such tools, viewing them as draconian punishment devices causing significant pain and distress to dogs. Modern electronic training can produce consistent low-level ES or vibrotactile stimulation that causes very little discomfort. Technically, the electrical output of modern e-collars is similar in principle to the ES produced by medical devices used to treat pain. The devices are generally easy to use and perform reliably and very effectively as a minimally aversive means for establishing escape/avoidance control through negative reinforcement. Leading manufacturers of such devices strive to produce radio-controlled training devices that operate effectively at low levels of ES—starting at levels that are barely perceptible to human touch. As the result of sophisticated design and circuitry advances, modern e-collars cannot burn or otherwise damage skin tissue, except as might occur as the result of electrode irritation. Klein (2000) performed a series of tests on various collars in which the electrodes were placed on porcine skin preparations. The highest electrical currents produced by the collars tested were repeatedly applied to the skin for 5 minutes, under both dry and wet conditions. The tests showed conclusively that the electrical current produced by the e-collars tested does not cause burns of any kind. Contemporary devices do not produce significant heat on the skin, even after prolonged and repeated stimulation at the highest levels. Various soft and pliable electrode materials have been developed in recent years that will hopefully help solve skin irritation problems in the future. Disposable conducting rubber or siliconlike caps placed over metal electrodes would potentially help to solve some of these problems.

Despite the relatively harmless and innocuous character of the stimulation delivered by modern electrical training devices, some veterinarians, behaviorists, and animal welfare authorities have alleged that such devices hurt dogs (Frank, 1999), burn the skin (Seksel,

1999), and promote harm to the human-dog bond and welfare of the dog (Schilder and Van der Borg, 2004). Many anti-e-collar campaigns have centered around misinformation supported by veterinary misdiagnoses regarding the capacity of e-collars to produce burns. At least one person has been unfairly prosecuted and convicted on cruelty charges stemming from accusations that a bark-activated collar she used severely burned her dog's neck (Wellington, 1999). In some quarters, there is considerable pressure under way to make the case that e-collars are cruel (Kisko, 2003), with some organizations virtually pleading for anecdotes and hearsay with which to build a case in lieu of a genuine body of scientific evidence. The following, presented before the British Parliament, is an example of the sort of disinformation that governing bodies are spoon fed with the explicit purpose of biasing their decisions and promoting restrictive legislation:

> Other cases include those of dogs that have been brought to vets with severe neck burns. Of course, it is always claimed that such injuries are the result of a malfunction of the collar rather than deliberate mistreatment. One inevitable cause of malfunction is that the electrical properties of an animal's neck are affected by how wet it is. (Rendel, 2003:column 870)

With respect to the first point, to my knowledge no recognized authority has claimed that skin irritation and lesions are the result of burns caused by a malfunction of a collar stimulator. The assertion that electrode lesions are caused by a collar malfunction is a straw-dog argument with no substantive evidence to support it. In fact, no one has ever proven that even the slightest burn can be produced by one of these devices. Of course, a simple series of experiments on an anesthetized dog would rapidly put the matter to rest, perhaps helping to prevent future misinformation, false charges of cruelty, and legal wrangling, such as recently occurred in the Australian federal courts. In that situation, statements made by a senior Australian Royal Society for the Prevention of Cruelty to Animals (RSPCA) inspector asserting that e-collars produced electrical shocks sufficient to cause severe burns prompted an e-collar distributor and a manufacturer to file suit seeking damages and to set the public record straight. The judge decided the case on the merits of testimony given by an electrical engineer retained by the respondents. The expert stated that although the open circuit electrical potential of the collar in question was indeed 2705 V, the actual voltage driving electrical current at the electrode-skin interface was estimated to be on the order of 2 V! As a result, the judge found that the public statements asserting that e-collars inflicted a 3000-V shock were, "in every sense, misleading or deceptive" (Federal Court of Australia, 2002), and decided in favor of the complainants and awarded the e-collar company $100,000 in damages. As previously discussed (see *Electrical Potential, Current, and Power*), the open-circuit voltage produced by these devices is rather meaningless for estimating the size and potential for harm delivered to a dog. The judge in making his ruling found that e-collars are incapable of producing burns (Brine, 2002).

To some extent, the apparent confusion regarding electronic training is due to a lack of working knowledge and experience with electronic training tools. Many critics appear to lump together all forms of ES, regardless of intensity, under the same rubric of an imminent potential for harm and malfeasance. This unscientific and irresponsible practice blurs significant distinctions between the effects of the radio-controlled ES produced by modern e-collars and the effects of traumatic electrical shock, as historically used in the laboratory to induce learned helplessness and traumatic behavioral adjustments, namely, shock capable of doing great physical and psychological harm. It is of utmost importance when discussing shock and ES to specify with some precision the level of stimulation to which one is referring. As noted previously, ES that is virtually imperceptible to human touch can be extremely effective for some dog-training purposes, just as HLES that produces localized and physically harmless pain can be effectively used to rapidly deter highly motivated and undesirable behavior. Electricity, like gravity, has varying degrees of intensity and potential to do biological harm. By way

of illustration, consider the very different effects resulting from the action of dropping a bowling ball on one's foot versus the effects caused by dropping a tennis ball instead. Although gravity mediates both of these actions, the pain and physical damage caused by the bowling ball would obviously be significantly greater than the effects produced by the tennis ball. Although electrical current delivered at high amperage can be life-threatening or produce significant burns, the ES levels most commonly used in dog training are extremely low, often being barely perceptible or producing a mild tingling or pricking sensation to human touch. A dog's experience is probably more akin to an annoying tingle (low level) or startling twitch (moderate level) sensation—not painful shock. Of course, at higher levels, the electrical output of such collars can be both painful and startling, but such stimulation is infrequently used in the context of electronic training.

Modern techniques and devices incorporating LLES are distinguished by the capacity to produce a graded and relatively harmless level of stimulation. Breland-Bailey (1998) has stressed that ES is highly controllable and can be precisely adjusted to meet exacting specifications. She argues that the controllability of ES recommends its use as a laboratory tool as well as a practical means for decreasing undesirable behavior:

> A. The amount of shock can be precisely determined and measured. It can likewise be precisely controlled so as to avoid physical damage and evaluate the amounts needed to achieve certain behavioral effects.
>
> B. This means that a shock need not be the same as hitting a fly with a cement block. It can be as strong or as weak as desired. Some ES can be so weak as to resemble only a slight tingling. Indeed, some human observers even report a mild, pleasant effect.

She then goes on to describe how such stimulation has been used to control self-injurious behavior in autistic and retarded children:

> This kind of electrical stimulation has sometimes been used in controlling self-destructive behavior in autistic and retarded children. It is not so much a punishment for such behavior, because the "shock" is so mild, as it is an alerting of the child that he is beginning to emit such behavior. If he then stops, his subsequent response can lead to positive reinforcement.

This description precisely captures how ES is most effectively applied in dog training.

Although uncontrollable shock and pain may produce significant stress and fear that can interfere with effective learning, the low to medium levels of ES most often used in the context of electronic training produce minimal distress and typically result in very effective, efficient, and lasting behavioral change. Dogs receiving such training usually exhibit very little distress or confusion; to the contrary, most dogs show signs of enhanced relaxation, confidence, and playfulness subsequent to electronic training. This practical observation is supported by many laboratory studies that have shown how escapable ES is followed by opponent emotional relief and relaxation—safety (Denny, 1971 and 1976). Many authors have emphasized the role of pathological anxiety and stress in the etiology of compulsive self-directed licking, but none have actually quantified the alleged presence of anxiety or demonstrated evidence of elevated cortisol secretion or other physiological markers of stress in dogs showing compulsive behavior. Assuming that anxiety and stress are significant factors in the etiology of such problems, and granting for the moment that ES is fear-eliciting and stressful for dogs, one would expect that such stimulation should increase licking behavior. However, as discussed previously, Eckstein and Hart (1996) found that remote ES reduced psychogenic licking significantly in several dogs, with no significant adverse side effects. Similar benefits of radio-controlled and behavior-activated ES have been found in treatment of aggressive behavior and separation-related excesses (see *Separation-related Problems and Punishment* in Chapter 4). Electrical stimulation in the treatment of behavior problems requires that the cynopraxic trainer/therapist possess appropriate technical knowledge and skills together with a sensitive appreciation for potential adverse side effects.

Electronic training has many potential applications in the context of behavior ther-

apy that remain unexplored, largely because of prejudice, misunderstanding of the process, and an exaggeration of the risks posed by electronic behavior therapy and training. An area of considerable interest for future practical application and research is the use of remote-controlled LLES, scentless spray, and vibrotactile stimulation in the context of puppy training, especially with highly impulsive and reactive young dogs showing excessive mouthing, biting, chasing behavior, aggressive tendencies, or social deficits not adequately responsive to food-based conditioning, play training, and conventional directive efforts alone. Although Polsky (1994) has suggested that ES might be used as a standalone modality for inhibiting "incessant" mouthing and biting in puppies, such training would be best applied in the context of appropriate reward-based efforts aimed at integrating excessive competitive behavior into an appropriate play outlet. Electronic training collars used for such purposes should be fitted with appropriate amplitude control (e.g., a voltage divider) to ensure that the ES delivered does not exceed a mild, attention-controlling level (tickle/tingle), even when delivered at the highest level. Early preliminary exposure to LLES may prove highly beneficial for hunting and working dogs, especially when electronic training is likely to figure prominently in adult training activities and fieldwork. The goal of early electronic training is to establish a positive bias toward ES as a controllable deterrent introduced within the context of reward-based training and play.

Aside from an incomplete understanding of the training process and lack of familiarity with electronic training devices, some of the irrational criticisms of ES may stem from phobic emotional and cognitive elaborations. For most people, the first experience they have with electricity is painful shock. Electricity is a common household hazard that parents repeatedly warn or punish young children about not approaching in order to instill fear and avoidance. Consequently, as the result of direct fear-eliciting experiences and fear-instilling parental warnings of the potential harm of electricity, most people are inculcated with a powerful aversion toward ES. The inculcation of negative associations with electricity is further magnified by the extreme images of electroshock therapy and electrocution that further bias people against the biological and psychological effects of ES. Other lasting fallout may stem from the use of electrified floors, belts with studs for the remote delivery of shock to buttocks, and the use of cattle prods to control the self-injurious behavior of institutionalized autistic and retarded children (see Lovaas et al., 1965; Lovaas and Simmons, 1969). In one of these studies (Lovaas and Simmons, 1969), children that banged their heads against walls, struck themselves, or bit into their skin were exposed to a brief (1 second) aversive shock delivered by a battery-powered "inductorium"—a cattle prod. The image of severely retarded children being repeatedly shocked with a cattle prod makes one cringe—the more so when the procedures are described in the emotionless and sterile language of a behaviorist. The emotional controversy provoked by the use of shock to control child behavior may have negatively biased the public's perception regarding the humaneness of ES for training purposes, whether for the control of children or dogs.

Future Prospects and Trends

When properly understood and employed, ES can be effectively used to modify dog behavior without eliciting significant stress or fear. Given the potential benefits of LLES for dog behavior control and the relatively harmless and innocuous nature of LLES, it is nothing short of appalling that so many respected authorities, who otherwise show evidence of intellectual integrity and scientific restraint, have chosen to condemn electronic devices, based on personal prejudice and the hearsay opinions of others. Some outspoken critics appear to lose all perspective and semblance of reasonableness when it comes to electrical training aids, accepting and perpetuating patently emotional and misleading arguments as matters of fact. Individuals who otherwise may strive to shape their opinions and attitudes in concordance with verifiable empirical

evidence betray their lax commitment to scientific method when they pronounce sweeping and unsubstantiated generalizations denouncing electronic training aids as inhumane tools that are used to abuse dogs. The same persons who reject LLES may embrace without question the use of highly intrusive restraint tools (e.g., halters and muzzles) or blast dogs at close quarters with compressed-air nautical horns without blinking. Considering the widespread incidence of dog behavior problems and the questionable efficacy of many current treatment strategies, one would expect greater open-mindedness with respect to tools (electronic and otherwise) that might offer significant and unexpected therapeutic benefits.

The manufacture and distribution of electronic training devices have become big business. Worldwide sales of e-collars for the year 1999 reportedly topped 3,000,000 units in that year alone (Holliday, 2000). Probably many more are sold today, with tens of millions of these devices in current use. In the United States, in particular, a growing number of professional dog trainers and dog behavior consultants have integrated electronic devices into their reward-based training and therapy programs as adjunct tools. Numerous public seminars and workshops are now dedicated entirely to providing the dog-owning public with detailed instruction on how to use electronic training devices effectively to promote desirable behavior and deter undesirable behavior. If a threat of harm existed at a population level, as alleged by critics, one would expect that many more dogs would have behavior problems and physical injuries stemming from the use of such devices, including various behavioral complaints involving fear and stress-related disturbances directly tied to electronic training. In fact, adjustment problems resulting from such devices are extremely rare and, in any case, most frequently found in association with behavior-activated systems, not radio-controlled devices. With respect to harm resulting from remote e-collars, to my knowledge there are no scientific reports that provide any proof of actual harm. Polsky (2000) has identified a possible risk of pain-elicited aggression with containment systems, but otherwise such devices appear to be relatively innocuous in comparison to other factors contributing to the development of behavior problems. There is currently no substantive evidence justifying claims of harm produced by electronic training devices, but there is significant evidence of benefit derived from the proper use of such devices for the control of undesirable dog behavior. Consequently, Scott-Park's (2002) suggestion that "there is little data available to prove either their misuse or positive applications" is only half right; in fact, as discussed throughout this chapter, there is substantial evidence of benefit in a variety of professional dog-training and wildlife applications. With respect to unsupervised owner use of such devices, one preliminary survey of dog owners in Australia indicates only minor adverse effects, primarily related to electrode irritations to the skin, with 97% of the respondents indicating that they were either satisfied or "more than satisfied." Among those respondents indicating that they were more than satisfied, 70% reported that they were "very satisfied" or "absolutely delighted" (Coleman and Murray, 2000).

Although the design and safety of electronic training aids have progressed significantly over the years, much still remains to be done to improve the effectiveness and humaneness of these various products (e.g., standardization of the electrical output of collars). Perhaps the most important area needful of attention is user education. Average dog owners typically lack the necessary training skills and appropriate behavioral knowledge to use remote e-collars effectively and safely to train their dogs. Manufacturers of such devices should make a dedicated effort to develop educational materials and programs, such as videos, interactive CDs, and instructional manuals, providing step-by-step instruction on the operation and use of the devices. Whenever possible, however, inexperienced dog owners should be encouraged to receive hands-on instruction from skilled trainers and other professionals experienced in e-collar use. Providing instructional seminars to retailers, trainers, veterinarians, breeders, and other dog-related professionals would be

a helpful means to disseminate pertinent information widely. Many e-collars are sold over the counter to dog owners with little by way of instruction on how to use them properly to train dogs or control a dog's undesirable behavior. The humane use of electronic training equipment depends on an educated end user; oddly enough, though, few manufactures have come to grips with their responsibility in this regard and, along with pet-supply retailers, appear content with the status quo and the short-term profits derived from the sale of these products to a relatively ignorant dog-owning public—a state of affairs that is difficult to fathom when one considers the high stakes. Eventually, this strategy may prove foolhardy, perhaps leading concerned individuals and organizations critical of such devices to seek legislative action to restrict their sale and use by the public, altogether.

As with any training device or technique capable of producing significant discomfort to dogs, trainers have an obligation to use the least intrusive and aversive means necessary to achieve necessary behavioral change. In addition to eschewing techniques that produce unnecessary distress and pain, trainers should be guided by an overarching spirit of kindness and respect for dogs. Despite such problems and limitations, little doubt exists that electronics in one form or another will significantly influence the future of dog training and dog behavior therapy. Further, as more trainers and behaviorists discover the usefulness of LLES, novel applications and advances for the use of radio-controlled and behavior-activated devices will certainly develop. The potential of training systems incorporating LLES and positive reinforcement to enrich the lives of companion dogs and improve their behavior will be limited only by the creative imagination of progressive trainers and the ingenuity of bioelectrical engineers to make such devices as painless as possible.

Cynopraxis: Theory, Philosophy, and Ethics

PART 1: TRAINING THEORY

WHAT IS CYNOPRAXIS?

The term *cynopraxis* combines the Greek roots cyno (*kunos*) or "dog" and praxis (*prassein*), meaning "to do" or doings with the dog. In accordance with Aristotle's use of the term, the notion of praxis consists of goal-directed action performed in accordance with three criteria: the action is voluntary, regulated by informed and rational choice, and performed as an end in itself (Irwin, 1985). More specifically, these *doings* refer to the collective exchanges and transactions between the trainer, dog, and family aimed at promoting interactive harmony, mutual appreciation, and an improved life experience with the dog. Cynopraxis is a pragmatic process constrained to the complementary goals of enhancing the human-dog bond while improving the dog's quality of life.

CYNOPRAXIC TRAINING THEORY

A successful training theory should possess a number of defining characteristics. The theory should be based on a limited number of processes, explain a wide range of related behavioral phenomena, and generate predictions that are testable by direct observation and experimentation. First and foremost, however, a training theory must successfully account for behavioral organization that simultaneously results in order and increasing variability as the result of experience. In addition, the value of such a theory depends significantly on how well its postulates and predictions connect with the factual and theoretical accounts of related disciplines, especially those already possessing a high degree of scientific veracity and maturity. As a result of such cross-discipline linkages, the explanatory significance of the theory is made more general, convincing, and useful. In particular, a training theory should be consistent with the experimentally established findings of formal learning theory and neurobiology, especially those findings that pertain to the organizing processes that contribute to the learning process. Finally, a cynopraxic training theory must satisfy a set of special requirements peculiar to the cynopraxic process itself to provide an explanatory account for the ability of cynopraxic procedures to facilitate competent social skills and change conducive to mutual appreciation, interactive harmony, and affectionate playfulness. A training theory need not be infallible, but theoretical conjecture and speculation should take a form that admits to the possibility of experimental falsifiability. Cynopraxic training theory appears to meet these basic requirements as well as possessing interesting implications for understanding human behavior and learning. An introductory orientation of the theory is provided in *A Brief Critique of Traditional Learning Theory* in Volume 1, Chapter 7.

BASIC POSTULATES, UNITS, PROCESSES, AND MECHANISMS

Cynopraxic training theory argues that instrumental behavior cannot be studied in isolation from affects, incentives, expectancies, and establishing operations, without losing its functional integrity and significance. On a very basic level, behavior is rewarded or punished as the result of its ability to predict and control the occurrence of

significant motivational events (see *Tolman's Expectancy Theory* in Volume 1, Chapter 7). Reward occurs when an action successfully controls the occurrence of an anticipated resource or threat, whereas punishment occurs when such control efforts fail. According to this viewpoint, successful actions serve to confirm prediction-control expectancies, whereas failed efforts disconfirm them. The success and failure of purposive action result in the evocation of emotional state changes that exert significant modulatory (excitatory and inhibitory) changes on behavior; contrary to the law of effect, however, these state changes affecting arousal, alertness, and action readiness are consequent to the effects of reward and punishment and are not themselves the cause of reward and punishment. Successful control is associated with surprise and increased excitability when the outcomes are better than expected, on the one hand, or comfort and safety and increased calming when the outcome is just as expected. By contrast, failure occurs when purposive action results in worse-than-expected outcomes. Failure is associated with disappointment and conflict between excitation and inhibition (distress) or *loss of comfort*, on the one hand, and increased apprehensiveness of danger and an aversion to risk, heightened vigilance, and a heightened action readiness to flee or hide in response to a *risk to safety*. Accordingly, the emotional effects or *affects* associated with adaptive learning are consequent to the confirmation or disconfirmation of prediction-control expectancies.

Thus, learning by reward and punishment is not simply a matter of confirming or disconfirming expectancies but proceeds in accordance with cognitive, emotional, and behavioral adjustments to discrepancies or *prediction errors* between what a dog expects to occur and what actually occurs as the result of its control efforts. According to this hypothesis, an important aspect of learning is the acquisition of reliable predictive information (knowledge) by testing prediction-control *hypotheses* (Tolman and Brunswik, 1935). Dickinson (1980) nicely summarizes the importance of prediction error and uncertainty for adaptive learning:

> It could be argued that there is something intuitively implausible about the central idea of Mackintosh's theory [see Mackintosh, 1975], the idea that animals learn about an event to the extent that it has been a reliable and good predictor in the past. Certainly an animal should control its behaviour on the basis of the information provided by such reliable predictors. It is far less clear, however, that the learning capacity of an animal should be largely devoted to processing events which in the animal's recent history have been constituents of stable relationships. Rather one might expect the animal to devote most of its processing capacity to analyzing events whose predictive significance is uncertain in an attempt to discover relationships involving these events. (153)

Cynopraxic training theory postulates two primary units of behavioral organization: the control module and the adaptive modal strategy. The *control module* consists of prediction-control expectancy, emotional establishing operation, and a goal-directed action. Prediction-control expectancies and calibrated establishing operations operate through the agency of flexible and purposive actions. When control modules are being integrated, positive and negative error signals encode changes to predictive expectancies and establishing operations that refine future control incentives and efforts. Prediction error also promotes excitatory and inhibitory motivational changes in the directions of increased or decreased approach or increased or decreased withdrawal. The emotional effects of reward (positive prediction error) mobilize active modal strategies (e.g., searching, exploring, and risk taking) whereas affects associated with punishment (negative prediction error) mobilize passive modal strategies (e.g., hesitating, ritualizing, and risk avoiding). Active modal strategies mobilized by the affective responses to positive error signals serve to orient a dog toward the source of reward to prolong contact with the location in order to derive information relevant to the control module. Passive modal strategies mobilized in response to negative prediction error serve to orient a dog away from the source of punishment or to hesitate before acting, again with the purpose of obtaining information relevant to error signals.

Adaptive modal strategies consist of both active and passive aspects mobilized in response to positive and negative prediction error in order to maximize resource benefits against costs and to manage competently the risk associated with unexpected windfalls and setbacks. In combination, control modules and adaptive modal strategies enhance a dog's ability to cope with the uncertainty of unexpected change by orienting and prolonging contact with valuable resources, as well as startling events, while extracting information to improve future control efforts. Many confident dogs engaged in an activity interrupted by a sudden startle will jump back to a safe distance (escape-to-safety response) from where they will often immediately return to the spot and cautiously investigate it to obtain information about the unexpected event. Such dogs respond to startle as an impetus to curiosity and increased exploratory activity, which is a pattern that they also show in response to novelty and attractive surprise.

PREDICTION ERROR AND ADAPTATION

Reward and punishment depend on the relative success or failure of instrumental efforts to anticipate and control motivationally significant events. Consequently, aversive and attractive motivational events share a common function of enhancing canine adaptability and security (comfort and safety) by promoting control incentives and goal-directed efforts, with aversive control efforts aimed at seeking and obtaining safety (relief and relaxation) and attractive control efforts aimed at seeking and obtaining appetitive and tactile gratification (comfort and calming). As such, reward-based training incorporates both aversive and attractive incentives presented and withdrawn in highly predictable and controllable ways. Just as stimuli paired with actions that anticipate the successful control of appetitive events are valenced with attractive significance, so are stimuli paired with actions anticipating the successful avoidance of aversive events (Dinsmoor, 2001); that is, they are both represented as reward signals. In an important sense, competent dog training is reward based regardless of the hedonic valence of the antecedent and consequent motivational stimuli used to activate control incentives and to facilitate behavioral change and control. A balance of controllable attractive and aversive contingencies in the context of social exchange promotes learning conducive to the integration of secure place and social attachments.

Prediction error results in significant alterations affecting social expectancies and mood. The direction of these changes depends on the relative proportion of surprising versus disappointing outcomes produced by control efforts. Dogs producing proportionately more surprises (positive prediction errors) than disappointments (negative prediction errors) tend toward elated mood and a positivity bias—changes reflected in a high level of optimism, confidence, relaxation, and persistence at tasks setting the occasion for prediction errors. Dogs operating under a positivity bias expect to produce positive prediction errors (reward). On the other hand, dogs producing proportionately more disappointment than surprise associated with social exchange tend to show dysthymic mood, irritability, and a negativity bias, as indicated by increased insecurity, anxiety and frustration, and a lack of persistence at tasks setting the occasion for positive prediction errors—dogs affected by a negativity bias expect to produce negative prediction errors (punishment) and conflict when they interact with people.

When properly performed, cynopraxic training provides a foundation of orderly interaction between the owner and the dog that can rapidly enhance mood and alter expectancy bias in the direction of increased optimism. The facilitation of an elated mood and an optimistic expectancy bias provides a valuable preliminary foundation for the implementation of more specific behavior-therapy procedures. In addition to improving an owner's ability to control and manage the dog, the highly predictable and controllable nature of training events helps to improve the dog's attention and impulse-control abilities—executive functions that are centrally involved in the organization of competent behavior.

Behavior resulting in a high degree of verification is relatively free of conflict and stress but lacks the excitement and surprise associated with the production of positive prediction errors. The safe and comfortable (but boring) status quo consisting of highly verified control modules are often put aside by dogs, at least momentarily, for the sake of exploring and experimenting, perhaps in search of unforeseen ways to exploit some resource more thoroughly, possibly discovering new solutions to old problems or taking risks with potentially dangerous situations, all in order to obtain the surprise and delight of producing positive prediction errors (cortical rewards). Reward resulting from better-than-expected outcomes helps to optimize prediction-control efforts. Contingencies of positive prediction error that are associated with adventure and discovery produce powerful incentives, sufficient to risk life and limb. Rather than resting content and enjoying the gratification of reliable and safe contingencies, cortical reward and punishment promote incentives to explore and take risks (active modal strategies), or to wait and minimize risks (passive modal strategies) if risk taking is unlikely to pay off.

Actions resulting in cortical reward cannot continue to produce reward by simply repeatedly producing the same rewarding outcome. Paradoxically, the more effective a response becomes, the less it can produce reward. This notion of reward conflicts substantially with the traditional formulation of the law of effect. In contrast to conventional assumptions, a central function of cortical reward according to cynopraxic training theory is to confirm the prediction-control expectancy while simultaneously producing surprise conducive to the mobilization of active modal strategies (e.g., increased seeking, searching, exploring, and experimenting). These observations point to another corollary of the prediction-error hypothesis: formally speaking, behavior cannot be certain to produce cortical reward; it can only increase the probability that a change will occur to produce surprise or relief. The most effective behaviors for this purpose are adaptive modal strategies, that is, a combination of active and passive modal strategies consisting of searching, exploring, risk taking, hesitating, waiting, and ritualizing. The aleatory nature of prediction error marks behavior in search of reward with a characteristic quality of hopefulness. Hope is the condition of behaving in accordance with uncertain, albeit expected, contingencies of reward (surprise), with hope occasionally being dashed by disappointment (see Mowrer, 1960).

Consequently, the surprise of cortical reward increases alertness and exploratory activity while orienting attention toward the windfall. As a result, the cortical reward does not simply increase the future probability of the reward-producing response but also serves to increase the probability of discovering information relevant to the optimization of the action. In addition to active modal strategies, passive modal strategies (e.g., waiting, begging, and ritualizing) are employed to decrease the likelihood of producing negative prediction errors. Passive modal strategies are especially likely to occur under conditions in which active strategies are more likely to produce negative prediction error than positive prediction error. The evolutionary provision of motivational incentives to activate environmental exploration and experimentation as well as to support waiting and ritualizing under adverse environmental conditions is consistent with the behavioral flexibility needed to optimize adaptability and survival fitness.

Learning by means of knowledge derived from experience and prediction error organizes behavior into a base of highly effective and reliable instrumental responses, routines, and patterns conducive to comfort and safety (order), while at the same time increasing exploration, experimentation, and risk-taking behavior (variability), thus optimizing a dog's ability to engage in competent exchanges with the environment. The advent of behavioral organization shaped by positive prediction error and negative prediction error heralds a sophisticated evolutionary advance that succeeds in organizing behavior toward increasing order while at the same time facilitating behavioral variability.

ADAPTATION, PREDICTION ERROR, AND DISTRESS

According to cynopraxic training theory, adaptive adjustments are organized to cope with the conflict and distress associated with error signals produced in association with the control of attractive and aversive motivational events. Control incentives operate in close association with prediction-control expectancies, calibrated emotional establishing operations, and goal-directed actions to prepare and enable a dog to obtain the full value of anticipated outcomes while managing risk and avoiding harm. The function of control incentives is to establish the value of available outcomes and thereby adjust effort to appropriate motivational levels, to increase or decrease a dog's tolerance for distress (frustration and anxiety), and to determine the amount of risk taking that the reward is worth.

Learning by reward and punishment depends on prediction-control expectancies functioning in close coordination with emotional establishing operations and abolishing operations (see *Instrumental Control Modules and Modal Strategies* in Chapter 1). Calibrated emotional establishing operations serve to modulate (excite or inhibit) control incentives in accordance with prediction error and a variety of cross-associative linkages between the event, action, and the hedonic value of the resulting exchange or *transaction*. These predictive relations are subject to constant revision and refinement in response to positive and negative error signals. The emotional establishing operation consists of specific motivational state changes that undergo continuous refinement in conjunction with the revision of prediction-control expectancies in response to prediction-error signals generated by goal-directed actions. In contrast, abolishing operations oppose the emotional and motivational effects of emotional establishing operations (e.g., fear and hunger) through the active inhibition of the motivational state evoked. According to this hypothesis, the inhibitory effects of abolishing operations serve to counter the emotional excitatory effects of establishing operations, but abolishing operations do not generate new motivational states incompatible with the disconfirmed expectancy. The pure inhibitory functions of abolishing operations point to an origin within the executive prefrontal cortex. For example, in response to an emotional establishing operation mediating fear or appetence, the abolishing operation actively inhibits fear and hunger but without replacing it with feelings of safety and comfort (satiation). The incompatible states of safety and comfort are mediated by emergent alternative emotional establishing operations developing in association with the integration of modified prediction-control expectancies.

The reward and punishment of control modules require that a dog be actively engaged in expectant efforts to control some significant attractive or aversive event. Significant events that simply happen to a dog out of the blue may produce temporary or even permanent conditioned excitatory or inhibitory effects on reactive modal behavior but not necessarily alter the control module. The organization of prediction-control expectancies requires the presence of antecedent signals to activate control incentives and preparatory emotional establishing operations in anticipation of the event in order to engage in efforts to control it. Without predictive signals to activate appropriate prediction-control expectancies and emotional establishing operations to guide changes of behavior at the critical moment, the dog may continue to repeat the same behavior over and over again, as Guthrie (1935) relates in a pertinent story that illustrates this aspect of expectancy learning:

> My own view of the way in which unpleasant or unsatisfactory consequences of action affect learning might be further illustrated by a minor incident in the routine of a certain psychologist. He rented an apartment for the summer with a garage which had a large swinging door. From the top of the door hung a heavy chain. Opening the door hurriedly the first morning the chain swung about slowly and struck a blow on the side of the subject's head, a distinctly painful and "unsatisfactory" event. But this continued to happen each morning for some two weeks. Why the long delay in learning to stand aside?
>
> The answer, I believe, is that the act of opening the door was performed while looking

> at the exterior of the door. The chain struck after the door had opened and the scene changed. Dodging was not conditioned on the sight of the door because a sight of the door had not accompanied flinching from the blow. The flinching movement which occurred as the rear of the car came into view was too late. Only after the bruised ear became a chronic reminder and the incident had been talked about and finally had been told to a visitor on the way to the garage, did caution show itself in time. (1935:159)

To intensify attention and to activate control incentives, many dog-training techniques involve the use of attractive or aversive events presented independently of a dog's ability to control them. As the result of such stimulation, attention is intensified and behavior activated into reactive seeking or fleeing modes. When such events are deliberately presented for the purpose of interrupting ongoing behavior, they are referred to as *diverters* (attractive events) and *disrupters* (aversive events) (see *Diverters and Disrupters* in Volume 1, Chapter 7). Diverters and disrupters are often linked to appetitive or emotional establishing operations and used as occasion-setting events to activate control modules incompatible with the interrupted target activity.

Comparator Processing, Allostasis, and Adaptive Optimization

Adaptive behavior is organized to cope proactively with the uncertainty of change. Anticipated outcomes are rarely exactly as expected but are sometimes slightly or far worse than expected, sometimes partly expected and partly unexpected, sometimes slightly or far better than expected, and sometimes more or less as expected. The sum effect of these outcomes is varied still further by diverse motivational states coincident with the outcomes produced. According to cynopraxic theory, predictive relations and transactions that produce positive and negative prediction errors are part of a reality-constructing process. The comparator processing of prediction error is hypothesized to represent an evolutionary opening out of neuroregulatory systems originally dedicated to track energy gains and losses maintaining physiological balance and homeostasis. The behavioral system includes a capacity to respond to error as alarm and warning signals triggering preparatory responses in anticipation of physical and psychological stressors as well as reward signals in anticipation of relief and comfort. Experiences of autonomic arousal triggered by emotional distress (frustration and anxiety), passive modal strategies organized to reduce loss and risk, and somatic reward (feelings of comfort and safety or security) are closely coordinated with energy conservation and homeostasis. Whereas homeostasis is concerned with the maintenance of physiological conditions within narrow ranges of deviation, allostasis mediates adaptive fitness by means of predictive relations shaped to maintain "stability through change" (Sterling and Eyer, 1988), a concept posited as an important evolutionary development in the way biological systems cope with change in the process of optimizing adaptability.

Adjustments to positive and negative prediction error enables dogs to optimize the extraction of useful predictive relations and patterns while limiting risks incurred as the result opening and exploring new things and places. The resulting *opening out* of experience is comfortable and safe (zona securitas) but sufficiently aleatory and dynamic (zona optimus) to maintain a feed-forward momentum, thus offsetting the adverse effects of internalizing (axipetal) and externalizing (axifugal) load. *Load* refers to a loss of adaptability stemming from a binding up biobehavioral energy into entropic activities that impair a dog's ability to initiate flexible control efforts in accord with prediction-control expectancies and calibrated emotional establishing operations (see *Big Bangs and Black Holes: Extraversion, Introversion, and Disorganizing Load*). Specifically, adaptability refers to the ability of dogs to integrate an expansive coping style (freedom) in the process of developing competent skills and the confidence to use them (power).

Feed-forward comparator processing links many different neural systems together into brainwide attunement networks and nodes

that resonate in response to prediction error and confirmation signals to organize adjustments relevant to adaptive needs (Simonov, 1994). The resulting organization is sufficiently complex and orderly to support energy homeostasis, while sufficiently uncertain and varied to enable dogs to cope flexibly with novelty and unexpected change by means of versatile control modules and adaptive modal strategies conducive to allostasis. A complex network of interconnective nodes links the orbital and medial prefrontal cortex (PFC) to the hypothalamus (Öngür et al., 1998), the head ganglion of the autonomic nervous system, which performs numerous integrative functions associated with autonomic attunement, appetitive and defensive motivation, reproduction, and energy homeostasis. In addition to hypothalamic projections, networks comprising the orbital-medial PFC have strong interconnectivities with the basolateral amygdala, basal ganglia, superior colliculus, hippocampus, the ventral tegmental area, the periaqueductal gray, and brainstem vagal system. Multiple levels of comparator processing work in unison to decipher patterns of significance (reward value) adhering to prediction error and to integrate the information obtained into an expanding interactive space opened and exploited in the process of optimizing adaptive skills. Such a layered comparator processing system is consistent with the notion of a behavioral guidance system comprised of cortical-autonomic attunement nodes that assign motivational significance (arousal, incentive, and hedonic value) to attractive and aversive events, select appropriate goal-directed actions, and mobilize adaptive modal strategies in response to error signals. Thus, sensory input processed for error and significance by frontal and limbic networks is projected to the hypothalamus to modulate complex neuroendocrine and autonomic effector systems. These reciprocal pathways between the cortex, limbic areas, and the hypothalamus give rise to a subjective awareness of emotion and motivational state changes via humoral, visceromotor, and afferent vagal feedback from the body (see Nauta, 1971).

The evolution of the neocortical mantle was probably related to adaptations necessitated by the added metabolic demands of thermoregulation. The increased metabolic costs of sustaining temperature homeostasis were met by a matching increase in the early mammal's ability to procure food and other basic survival resources via predictive information and environmental maps organized by the cortex. Interesting, within the developing embryo, the first part of the neocortex to develop is localized around the mouth, with the remaining development of different cortical areas concentrically building out from this core area (Allman, 2000). An increased capacity for organizing behavior in accord with prediction-control expectancies and calibrated establishing operations is hypothesized to be the result of a revolutionary shift from reactive adjustments to internal and external demands to a more flexible and proactive pattern of *adaptive optimization*. This shift toward the organization of behavior in accordance with prediction error and an increased awareness of internal emotional states is likely a result of evolutionary changes to the mammalian brain organized to cope with the complex demands of social life and the extended care of offspring. Awareness of one's emotional state of arousal is a necessary precondition for the hesitation and proactive adjustments needed to avoid conflict, enabling dogs to wait and delay or to select alternative courses of action. Choosing among alternative courses of action probably traces its origins to a habitual pattern of hesitating and refraining to act immediately in anticipation of social exchange, thereby giving rise to an ability to consider and rehearse various control options in advance of initiating action based on the option that *feels* best (more likely to succeed or safer). The ability to hesitate and choose or wait provides dogs with a strong element of voluntary control over social exchange. By means of *feel*-forward comparator processing, emotional establishing operations are calibrated to meet the anticipated needs of ongoing goal-directed projects and ventures based on affective adjustments to prediction-control expectancies and action-mediated prediction error.

The process is analogous to the operation of a radio. A radio is designed to detect and decode subtle patterns of information encoded into electromagnetic signals that are transmitted at the speed of light through the atmosphere, picked up, separated, and conducted through various feed-forward circuits in the process of decoding, converting, and amplifying electromagnetic information into acoustical signals delivered at a rate and strength to enable the listener to experience a coherent and realistic pattern of acoustical stimulation represented to awareness as crystal clear music. A major difference between a radio system and the adaptive brain system is related to the processing of prediction error. Everything governing the operation of the radio is highly predictable and closed. A radio cannot improve over time but merely wears out. The canine brain is designed to improve senso-effector capacities over time by means of adaptive adjustments in response to prediction error. Accordingly, prediction-error signals are converted into energy/information values (energy gains and losses) and uploaded into feed-forward comparator processors that amplify the energy/error signal, converting it into feed-forward predictive relations having information and hedonic value. These energy/information values are selectively amplified while their significance is being determined and thus reach various cognitive (orienting and attending), emotional (arousal, incentive, and valence), and behavior (action mode) threshold values.

Control efforts result in a transfer of energy, the result of which is to open space and to optimize energy gains and losses via the organization of predictive relations. According to this general hypothesis, the moment-to-moment predictive relations that guide goal-directed efforts result in either better-than-expected or worse-than-expected outcomes (i.e., energy gains and losses relative to energy expenditures). These energy gains and losses are scaled and converted into changes of affective awareness and arousal having motivational relevance for ongoing control efforts. Consequently, the discovery of motivationally significant events while engaged in exploratory exchanges with the environment results in incentive (need) and hedonic (like and dislike) changes that increase autonomic arousal and invigorate attention (awareness) commensurate to energy gains or losses calculated to have resulted from the transaction.

Actions are not dissociable from feed-forward comparator processing but are the voluntary and goal-directed manifestations of such processing; that is, adaptive behavior is a complex energy/information exchange system that includes information collecting, processing, and testing functions. Technically, actions are not separate from experience but exist to mediate experience to acquire knowledge. *Experience* is understood as an active process of signification mediated by behavioral experiment, as in sense of the Latin, *experientia*, “knowledge gained by trial and test.” Actions can shape objects but cannot be shaped into objects. Behavior is an activity in constant change, and only a dead dog “behaves” like an object. As such, behavior lacks an objective nature except as regards the history of effects that it leaves on objects. Behavior can produce knowledge by virtue of exchanges with objects (culture) but cannot be known itself accept as a subjective experience of hedonic value, referred to as *appreciation*. During social exchange, the partner’s behavior is the object of esthetic and empathetic appreciation. Learning in accord with the formation of prediction-control expectancies is conducive to the development of increasing social awareness, appreciation, and competence.

Behavior consists of exchanges and transactions with the environment that open and extend fields of predictive relations into the uncertainty of change by collecting, processing, testing error signals. Thus, goal-directed actions are integrated into a stabilizing matrix of prediction-control expectancies and emotional establishing operations or control modules. The feed-forward comparator processing and amplification of error signals as experiential information mediating adjustment is conserved across distant phyla, ranging from conditioned reflexive adjustments to conscious awareness. The nature of such processing is limited by the complexity of the organism’s nervous system. With every level of comparator processing, the significance of the error

signal is extracted and amplified. During highly significant events, the error signal attains affective significance by its representation to awareness as an experience possessing hedonic value. The comparator process involves a complex interactive system of brainwide networks that cooperatively convert and amplify prediction error into significance, with experiential events of significant value attaining to subjective awareness after reaching threshold values prompting attentive interest or concern. Accordingly, habituated stimuli do not attract attention or evoke emotional arousal rising to awareness because they fail to rise above the preattentive sensory threshold of significance. Dishabituated stimuli are represented to experience as significant events by attaining to the threshold value of error signals prompting attention and interest.

The theory postulates that all categories of experience, including sensation, perception, cognition, emotion, and action, are the result of feed-forward comparator processing that extracts, amplifies, and interprets the value and significance of error signals. Error signals reaching preattentive thresholds (saccades) precede sensory and perceptual thresholds (orienting), sensory and perceptual thresholds precede cognitive thresholds (attention), and thresholds of cognitive significance precede affective thresholds attributing hedonic value (conscious awareness and appreciation). Thus, feed-forward comparator processors and dedicated algorithms convert sensory and cognitive values into affective or hedonic values (likes and dislikes) that in turn vector control incentives (needs) on objects of interest or concern with an intent to control them. The attainment of esthetic and empathetic appreciation represents the highest level of comparator refinement and amplification of error signals reaching thresholds of conscious awareness.

The organization of different predictive relations into a unified system entails that some common scalable and interchangeable factor or constant hold between them. The energy gains and losses resulting from social transaction may be scaled, encoded, and invested with value, as information, emotion (incentive and distress), and hedonics (energy gains and losses experienced as pleasure or displeasure). Accordingly, positive prediction error yielding surprise and elation (energy gain) results in an enhanced state of awareness, whereas outcomes that merely match expectancies are encoded to yield feelings of comfort and safety. As such, both attractive and aversive events have allostatic and autonomic value insofar as they evoke arousal/alertness and activate comfort- or safety-seeking action modes. This hypothesis suggests that sensory and emotional experiences are differentiated in terms of the neural energy expended to represent them as subjective experiences, with excitatory events appearing to require a greater expenditure of energy to represent than inhibitory ones. Whereas excitatory events carry an attractive or aversive valence that generates an increased vigilance and readiness to act, inhibitory events conduce a state of autonomic dearousal (Collet et al., 1999). Finally, there is an optimal level of attractive or aversive arousal that promotes adjustment and reward, stimulation under or over which evokes irrelevant or conflictive responses (Hebb, 1955).

Somatic versus Cortical Reward, Projects and Ventures, and Power Incentives

The integration of prediction-control expectancies, calibrated emotional establishing operations, and actions into control modules gives dogs a significant degree of choice in defining and pursuing goal-directed objectives, referred to as *projects* (riskless) and *ventures* (risky). Although adaptive behavior is responsive to the motivational influences of emotional command systems, according to cynopraxic training theory, autonomic arousal and modal activity evoked by conditioned and unconditioned attractive and aversive motivational stimuli do not directly regulate behavior by means of reinforcement and punishment, but instead motivational events generate control incentives (e.g., hunger, thirst, fear, anger, and loneliness) and distress (frustration and anxiety) in association with excita-

tory and inhibitory state changes that alter alertness and action readiness.

Technically, reward and punishment refers to the relative success or failure of goal-directed projects or ventures to control significant motivational events. Control efforts that match expected outcomes confirm or *reinforce* the control module. Although such matches or somatic rewards may verify control modules, gratify control incentives, promote relaxation, and generate security (comfort and safety), they do not add anything new to a dog's ability to predict or control the event; that is, they do not reduce uncertainty adhering to change. Since the verified action is asymptotic in its capacity to produce reward, verification establishes an increasingly stable plateau of order (see *Reinforcement and the Notion of Probability* in Volume 1, Chapter 7). Verifying events serve to gratify dogs motivationally and to maintain the status quo—a condition of no change and no need to change. Under highly verified and regimented environmental conditions, learning may be significantly impeded by a lack of sufficient prediction error to produce cortical reward. The reduction in reward under such circumstances may produce various deleterious and damaging behavioral effects paradoxically despite a high degree of order and adequate basic resources and safety from danger. For example, a dog may engage in risky sensation-seeking behavior to raise the intensity and variety of stimulation to obtain positive affects from social exchange.

Whereas the confirmation of a control module results in reinforcement (verification), the disconfirmation of a control module results in its rapid or gradual extinction. *Rapid extinction* occurs as the result of the signaled discontinuation of the instrumental control contingency, with the previously rewarded behavior now failing to control the aversive or attractive motivational stimulus. In contrast, *gradual extinction* occurs as the result of an unsignaled discontinuation of the control contingency such that a significant amount of uncertainty remains regarding the status of the contingency. In addition to disappointment and discomfort, the gradual extinction of a control module produces significant anxiety and frustration associated with uncertainty. Avoidance learning is particularly problematic in this regard. An unsignaled discontinuation of an avoidance contingency gives a dog little information about the necessity of the avoidance response. Since the dog cannot know whether the avoidance response is necessary without testing the contingency by withholding the avoidance response, it may continue to perform the response long after it is unnecessary to do so. Consequently, in order to learn the status of the avoidance contingency requires that the dog take risks and test it periodically by withholding the avoidance response or forgetting to respond. In highly aversive or traumatic events, the risks are so great that dogs may persist in the avoidance response indefinitely rather than test the contingency, obtaining significant reward from the safety produced by the strategy. The major difference between rapid and gradual confirmation and disconfirmation of learned behavior is the relative degree of certainty that the dog possesses regarding the status of the control contingency.

Many common behavior problems stem from inconsistent efforts to disconfirm and extinguish social control modules and routines operating in association with intrusive modal strategies (e.g., begging and attention seeking), thereby producing significant positive prediction error and reward when the dog unexpectedly succeeds in compelling the interactive partner to yield more than he or she may wish to give, a disruptive source of reward that serves to increase intrusive limit testing, demanding behavior, and social risk taking. Consequently, the gradual disconfirmation of control modules and routines may provide a problematic backdrop for inadvertent reward, invigorate undesirable modal strategies, generate significant anxiety and frustration associated interactive conflict, and support vicious-circle behavior (i.e., increasing persistence associated with escalating punitive efforts). As a result of these problems, rapid disconfirmation via the signaled discontinuation of the control contingency is usually preferred to gradual extinction, not simply because it is faster acting (a criterion that is

not always consistent with long-term interests), but because it minimizes the risks and side effects associated with inconsistent extinction efforts. Although the disconfirmed instrumental control module is taken out of service, it is not unlearned or removed from storage, and it remains available for future use should it be needed. Alternative control modules are generally trained to replace undesirable behaviors associated with problematic or excessive modal behavior (e.g., attention seeking and begging). In an important sense, cooperation is simply attention-seeking and begging routines refined by training and established rules or control contingencies that set limits on the opportunity to gain the social and appetitive rewards sought by the dog.

When purposive control efforts produce better-than-expected or worse-than-expected outcomes, feed-forward comparator neural processors detect the mismatch and extract energy/information from the error signal. In contrast to the calming and relatively neutral emotional effects of somatic reward, the comparator processing of positive prediction error yields state changes that range from elevated interest and concern to power elation and emotional relief. As the error signal rises to the significance of hedonic value and *cortical reward*, it is encoded into comparator network nodes and engrams that inform prediction-control expectancies and calibrated establishing operations. The revision and optimization of the control module are associated with increased alertness and attention, vectoring reward value on the action and context producing the surprising event while activating adaptive modal strategies.

Neuringer (1969), for example, demonstrated that pigeons and rats would engage in key pecking and lever-pressing actions to earn food, even though the same food was made freely available to them within the experimental chamber (see *Contrafreeloading* in Volume 1, Chapter 5). These findings are consistent with the notion that successful control efforts are valenced with positive hedonic value and that the organization of adaptive behavior by reward does not depend on the satisfaction of needs or the escape/avoidance of danger but instead depends on a hedonic factor derived from the successful control of significant events: "Responding for food, like play and exploring, appears to be a natural part of the behavior of animals and does not necessarily depend upon any prior motivating operation.…the present findings suggest that animals often emit instrumental responses which reduce no biological need and abolish no threat" (401). According to cynopraxic training theory, exchanges yielding positive hedonic value serve to promote active modal strategies (exploring and experimenting), whereas outcomes or exchanges yielding negative hedonic value and increased risk promote passive modal strategies (e.g., hesitating and ritualizing). The differentiation of adaptive modal activity into active and passive strategies in response to positive and negative prediction error promotes behavioral variability, thereby improving a dog's ability to exploit unexpected windfalls while exercising appropriate caution and restraint.

From the perspective of adaptive optimization, reward (power/energy gain) and punishment (power/energy loss or risk) are both viewed as having positive significance insofar as they contribute information that refines a dog's prediction-control efforts. The essential difference between them from an experiential viewpoint is subjective; that is, reward is experienced as a gain having positive hedonic value (pleasure and power elation), whereas punishment is experienced as a loss or risk having a negative hedonic value (displeasure and power deflation). Actions that succeed in establishing effective control over a significant resource acquire positive hedonic value, whereas actions that fail acquire negative hedonic value. A principle difference between the occurrence of unexpected attractive motivational stimuli and cortical rewards yielding hedonic value is *power*. Attractive and novel events that merely happen to a dog may yield significant changes that affect arousal and modal behavior but not yield significant hedonic value. In the absence of purposeful control efforts guided by expectancies and establishing operations, such events will tickle the appetite with desire but not satisfy it. Thus, impulsive and hyperactive dogs are driven to seek novelty and reward relentlessly and recklessly but

cannot be satisfied so long as their control efforts are performed independently of control modules and power incentives. Such intrusive and exploitive dogs (unstable extraverts) epitomize behavioral powerlessness. In contrast, cortical reward and power elation are the result of occasions that anticipate opportunity and the successful optimization of control modules organized to exploit it.

The combined cognitive and hedonic effects of reward and punishment are reflected in autonomic changes affecting mood (lasting tonic effects) and feelings (transient or phasic emotional effects) conducive to selective attention, impulse control, attachments, and power. *Power* is defined as the acquisition of competent social and motor skills and the confidence to use those skills to optimize control over significant attractive and aversive events. As such, power conduces a state of optimism and increased action readiness (voluntary initiative) to practice and develop adaptive skills. Power is tempered by timing (hesitation and delay) and expansion into novel domains through skilful exploration, experimentation, and discovery aimed at maximizing the success of control efforts while minimizing risks and losses. Power is embedded in timely events that open space and invigorate emergent freedom incentives.

The cynopraxic training process enables the human-dog dyad to pursue an enhanced life experience by organizing social exchanges that mediate mutual appreciation and interactive harmony. Interactive harmony depends on the mutual acquisition of power by social partners to engage in social exchanges free of stressful conflict dynamics. Under the combined influence of power and freedom incentives, competent social exchange systematically increases the complexity and hedonic quality of proxemic relations while expanding the range of interactive relations into the living space by means of increasing cooperation and compromise.

Expectancies, Emotion, and Stress

The ability to regulate emotion adaptively depends on the coordinated refinement of prediction-control expectancies and calibrated emotional establishing operations. The discovery of a discrepancy or mismatch between what a dog anticipates and what actually occurs as the result of its action is adaptogenic; that is, both surprise and disappointment prompt adaptive change (see *Autonomic Nervous System-mediated Concomitants of Fear* in Volume 1, Chapter 3). Control modules resulting in worse-than-expected or less-than-expected outcomes (negative prediction error) produce anxiety or frustration in proportion to the degree of the detected discrepancy, whereas better-than-expected outcomes (positive prediction error) produce surprise and power elation. The adaptive anxiety and frustration associated with negative prediction error exert varying levels of inhibitory or excitatory emotional change that mobilize behavioral adjustments via the activation of the behavioral inhibition system (BIS) or the behavioral approach system (BAS). As the match is secured, the evoked frustration and anxiety are reduced in association with relaxation and feelings of comfort and safety. According to this hypothesis, comfort and safety result from adjustments that reduce frustration and anxiety by producing *as expected* outcomes, that is, outcomes that match or verify prediction-control expectancies. Rewards producing comfort and safety promote security and a calming effect in association with passive coping strategies (e.g., hesitating, waiting, and watching) and the avoidance of punishment (i.e., the loss of comfort or safety). The calming effect associated with enhanced comfort and safety appears to be mediated by the parasympathetic branch of the autonomic nervous system (ANS), suggesting the term *somatic reward*. In an important sense, somatic reward serves to mediate adjustments conducive to both behavioral and biological adaptation (homeostasis) via the reduction of error signals generating frustration and anxiety.

The reward associated with positive prediction error mobilizes intrinsically rewarding active modal strategies (e.g., seeking, hunting, and exploring), increased excitement and alertness, and elated mood via the activation of dopaminergic mesocorticolimbic reward

pathways. The surprise associated with better-than-expected outcomes mediates adaptive optimization (order with variety) and is referred to as *cortical reward*, emphasizing its executive organizing, exciting, and mood-enhancing effects. Learning is stressful but less so to the extent that adjustments are gradual and voluntary, based on reliable prediction-control expectancies, and organized in a social environment (home) generally perceived as safe and supportive. The ability to competently organize behavioral output toward the optimization of somatic and cortical rewards while avoiding punishment (loss of comfort and safety) is referred to as an *adaptive coping style*. Dogs showing adaptive coping behavior efficiently select control modules, monitor and assess outcomes, and make appropriate adjustments in accordance with prediction-error discrepancies.

When an established social expectancy is disconfirmed in a dramatic, threatening, and uncontrollable way (loss of trust), a dog's behavior may rapidly fall under the influence of stressogenic emergency arousal (fear or anger) and the activation of species-typical autoprotective coping strategies. Whether the dog confronts the threat, backs down, attacks, or runs away depends on the nature of the provocation, the size of the perceived discrepancy and amount of threatened loss or harm, the strength of elicited aversive arousal (anger or pain), the quality and strength of affiliative buffers (effect of person), protective quality-of-life (QOL) factors, behavioral thresholds controlling flight-or-fight behavior, acquired ability to regulate emotion, outcomes of past agonistic encounters, and so forth. In general, the way dogs respond to social threats and challenges can be divided into five types depending on reactive thresholds (see *Behavioral Thresholds and Aggression* in Volume 2, Chapter 8). Most dogs will cower to the ground and become immobile (high-flight and high-fight thresholds—type 1), others may attempt to run away (low-flight and high-fight threshold—type 2), some may stand their ground and confront the challenge but not attack unless provoked (high-flight and medium-fight threshold—type 3), some may attack without hesitation (high-flight and low-fight threshold—type 4), and a few may respond with panic and rage (low-flight and low-fight threshold—type 5). If a dog's efforts to escape are thwarted, an attack threshold may be rapidly reached, and under the influence of escalating fear and anger, a panicked attack with rage may follow. A dog that is prepared to confront a challenge or threat may hold ground but rapidly attack if reached for or grabbed, and escalate the attack in accordance with the perceived degree of threat. As the result of such agonistic encounters, reactive thresholds may be significantly altered, and the dog may become more reactive under similar future circumstances. Also, after experiencing a disconfirmatory mismatch between expected outcomes and actual outcomes, a dog may exhibit an increased dependence on direct sensory input for assessing the situation, appearing to lose its trust in expectancies for assessing social safety (see *Practical Example* in Volume 1, Chapter 7).

AUTONOMIC AROUSAL, DRIVE, AND ACTION MODES

At a basic level, acting in accord with modal drive is intrinsically gratifying, whether it results in approach and seeking or withdrawal and avoiding behavior; however, thwarting drive behavior is intrinsically annoying regardless of its motivational direction. For example, preventing a dog's flight to safety while operating under the aversive arousal of a threat will likely increase the direction and pressure (control incentives) of its escape efforts with frustration (annoyance). In contrast, behavioral exchanges that result in an unexpected opening to safety while under the added aversive arousal of annoyance may produce a pleasurable surprise consisting of elated relief and an emergent state of relaxation that yields feelings of safety. The reward associated with successful escape to safety promotes the integration of prediction-control expectancies, emotional establishing operations, and avoidance behaviors that lead to safety when exposed to similar future threats and circumstances. Likewise, preventing a hungry dog from taking food placed within its reach is annoying, whereas allowing it to

approach and eat the food is satisfying. Forbidding a dog to approach and eat appears to increase appetitive drive and control incentives via the aversive motivational effects of annoyance (frustration) under the modulatory influence of risk monitoring and anxiety. As the result of increased modal activity and mobilization of control incentives, those behavioral efforts that facilitate access to the food will be strengthened by reward, especially so in the case of novel solutions that the dog discovers as the result of experimenting or struggling under the pressure of distress.

Although the various action modes, drive, and emotional command systems are functionally partitioned, they are not entirely insulated and appear to exert a variety of excitatory and inhibitory influences on one another (see *Emotional Command Systems and Drive Theory* in Chapter 6). In contrast to the relatively strict segregation of quiet and affective attack modes, seeking and fighting modes do not appear to be strictly incompatible (see *Intraspecific State and Trait Aggression* in Chapter 8), whereas social and appetitive seeking and flight modes do show evidence of reciprocal inhibition, as evidenced by the psychogenic anorexia induced by social anxiety. In addition to diagnostic significance, the foregoing observations are of considerable relevance with respect to the benefits and drawback of appetitive counterconditioning as a therapeutic tool for reducing the reactive arousal anticipating certain forms of extrafamilial aggression. Behavioral treatment programs that exclusively rely on appetitive counterconditioning may reduce social anxiety (defense drive) without significantly reducing social anger (fight drive). For example, a mature watchdog when threatening a visitor fully expects that the target will retreat or that the target will fight back. At such times, the dog is attuned with autonomic arousal to engage the visitor in combat—not to make nice—so the presentation of food at such times is entirely out of context. With encouragement, some of these dogs will happily take food from the stranger but still remain in a reactive state of suspicion and suspense. The persistent wariness and readiness of such dogs to attack is only natural when one considers the circumstances and that only a few moments before they were engaged in behavior that established an adversarial relation with the visitor. Actually, the food-giving behavior of the visitor might be interpreted by the dog as a ruse to cause it to lower its guard, thereby making it vulnerable to a surprise attack. As the dog takes food, anxious arousal associated with defensive flight modes may be attenuated, allowing the visitor even to pet the dog without reducing the risk of an attack. The instant the visitor stops feeding or petting the dog or engages in overt actions (stands up) perceived as a threat, the change may trigger a strong catastrophic escalation of aggressive arousal.

When under the heightened arousal of drive compatible with the activation of seeking and prey-catching activities, the opportunity to chase a deer is intrinsically energizing and gratifying for a dog whether the chase succeeds or not, whereas compelling a dog to abstain from chasing a deer is intrinsically annoying. In addition, even though restraint is annoying, it will not help to reduce the future strength of the deer-chasing action mode. Accordingly, mere annoyance is not synonymous with punishment. Annoyance actually may significantly augment arousal and drive while generating more of the predatory action mode by virtue of agitation effects on drive. For example, the use of passive leash restraint (horizontal hanging) to block impulsive control efforts (e.g., seeking, chasing, and fighting) appears to escalate drive significantly by invigorating sympathetic arousal and energizing action modes. The action mode selected is determined by the combined pressure and direction of the motivational event, so that attractive events evoke comfort-seeking incentives and serve to activate approach modes, whereas aversive events are valenced to evoke withdrawal and safety-seeking action modes (escape to safety). A dog may shift from one mode into another under the combined influence of distress (frustration and anxiety) and increased aversive stimulation, thereby recruiting more energetic arousal and effort (escape from danger) with the goal of overcoming the interference blocking the

dog's access or ability to produce a situational change promising to confer comfort or safety.

Efforts aimed at thwarting motivated behavior without first causing a dog to disengage impulsive control efforts are generally unsuccessful. The amplified energetic state changes produced by holding the dog back on leash, for example, are encoded into emotional establishing operations signaling the dog to try harder, thereby increasing the strength of seeking and fighting modes and causing the dog to escalate its efforts when faced with similar circumstances in the future, making the impulsive pattern dominant over other coping options. Forcing a dog to stop an attack risks fanning the fierceness of the attack, just as blocking a dog's escape efforts may cause it to abruptly transition out of the flight mode into a fight mode. Finally, withdrawing social stimulation while a dog is in social drive is intrinsically annoying, whereas providing social attention at such times promotes social attraction and attachment. These are but a few of many linkages between modal activity, autonomic arousal, and drive that impact significantly the efficacy of behavior therapy.

The emotional effects of reward and punishment are closely integrated with the activation and deactivation of relevant drive modes. In addition to the differential effects of attractive and aversive arousal, as reflected in active and passive modal strategies, drive activity can be excited or inhibited by natural triggers or by classically conditioned stimuli. Also, drives can be modulated or interrupted by deliberately educing other drives. Drive deficits and excesses can be manipulated toward equilibrium by educing compatible (excitatory) and incompatible (inhibitory) state changes via the activation of relevant emotional command systems. Teasers are arousal-enhancing tools that are used to tune and boost activity or to attract a dog's attention with repeated lip smacking, clapping, changes of pace, crouching, and sundry other gestures. Drive eduction is often performed by means of diverters and disrupters (generic establishing operations) used to interrupt or balance drive-related activities. A cautionary note here is that stressing excessive reliance on training methods that reduce drive activity by educing incompatible drive (e.g., educing fear to decrease appetitive seeking) may introduce imbalance and destabilize the emotional command system, especially if such stimulation is applied severely or unpredictably or in the absence of stabilizing reward-based training efforts.

Drive and emotional command systems combine to give control incentives direction, pressure, continuity, and momentum, but only actions integrated into control modules are amenable to the effects of reward and punishment. However, reward appears to be more directly related to the hedonic value attributed to transactions rather than the gratification or drive reduction obtained by eating (Young, 1955) or escaping to safety. The actual eating of food and the escape to safety might mediate modal alterations and state changes (relaxation), but such consummatory effects alone may not mediate reward effects. For example, an anticipated food reward that is *bigger* but less savory than expected might actually be represented as a disappointment, whereas a food reward that matches expectations may prevent extinction but fail to support additional learning. Thus, reward appears to be more directly related to the hedonic value of the outcome (Young, 1959) and its capacity to optimize goal-directed efforts than its ability to satisfy a need. Consequently, increasing appetitive drive by food or social deprivation is not typically a very useful way to augment counterconditioning or instrumental control efforts. Alternatively, instead of increasing need (incentive value), a far more valuable effect can be achieved by increasing the hedonic value of the reward (i.e., by use of a more savory food item) or by switching to a different type of reward (novelty) to increase the enjoyment value of the reward object. The manipulation of hedonic value and novelty provides a powerful means to enhance reward value and increase the therapeutic value of food rewards (Zernicki, 1968).

Crespi (1942) showed that the reward value of food can be increased or decreased by changing its size during a post-training test phase relative to the size of the reward used in

the training phase. Initially, Crespi trained three groups of rats to run to a goal box where they received 1, 16, or 256 pellets, respectively. These groups were subsequently tested and compared for motivational differences by giving each of them 16 pellets and then measuring running speed. The experimenter found that rats trained with 16 pellets showed no change in running speed, whereas those that had been originally trained with 1 pellet showed a significant increase (elation effect) in running speed, and those trained with 256 pellets showed a significant decrease (depression effect) in running speed. These findings are consistent with the expectancy hypothesis, whereby a bigger-than-expected outcome (positive prediction error) generates surprise and elation, thereby increasing the hedonic value of the food reward, whereas a smaller-than-expected outcome (negative prediction error) produces disappointment and depression, thereby decreasing the reward's hedonic value.

Actions operating under the guidance of prediction-control expectancies and calibrated emotional establishing operations (control module) are refined or *optimized* by social and environmental transactions that yield surprise or disappointment. Further, the hedonic value of any given transaction is determined by the difference between the gain anticipated from the energy invested in the action and the actual gain produced, less the energetic costs and risks incurred by pursuing the project or venture. Energy is invested in behavioral projects and ventures with an expectation of a profit. Consequently, the optimization of control modules is closely coordinated with an *unconscious* process organized to maximize energy gains while minimizing energy losses and reducing risk. Energy gains and losses are encoded into conscious awareness as pleasurable or displeasurable alterations commensurate to the positive or negative hedonic value of the outcome. Energy gains and losses (i.e., physiological state changes) are scaled or translated into affective state changes that rise to the level of awareness by the amplification error signals provided by feed-forward comparator processing networks that simultaneously construct an experiential engram that informs and modifies the control module. According to this hypothesis, the energy gains and losses inferred from positive and negative prediction error are represented to awareness as affective changes having hedonic significance. These affective changes rise to awareness as substrate neurophysiological alterations are integrated into synaptic elaborations or attunement nodes and nodal networks that alter synaptic sensitivity and mediate long-term reverberation and resonance effects affecting mood and action readiness. The composite synaptic activity of attunement nodes and nodal networks, and corresponding effects on mood and a dog's readiness to initiate voluntary action, are hypothesized to vary depending on the proportion of transactions perceived as resulting in energy gains (positive hedonic value) or losses (negative hedonic value).

The ability of an attractive or aversive motivational incentive to promote instrumental learning depends on its ability to generate sufficient emotional arousal to mobilize an appropriate control module without being so strong that it triggers reactive adjustments. The generation of emotional arousal via the presentation of attractive (appetitive and social) and aversive stimuli varies greatly among dogs. These breed and individual differences reflect the combined influence of genetic predisposition and prior experience on social approach-withdrawal thresholds (social temperament dimensions), coping styles, transient motivational states (e.g., isolation and hunger), survival-mode activity, and autonomic attunement. Dogs combining low-approach and high-withdrawal thresholds consistent with *extraversion* are more likely to persist in conflictive social exchange under the influence of escalating autonomic arousal yielding frustration, whereas dogs expressing high-approach thresholds and low-withdrawal thresholds consistent with introversion are more likely to withdraw from social conflict under the influence escalating arousal yielding anxiety. These tendencies to persist or withdraw in response to conflict exert potent organizing effects on social behavior, mood, and coping styles.

The preference shown by extraverts for signals of reward, novelty, and risk taking predis-

poses them to acquire proactive skills that tend to individuate leader personality traits and roles in association with confidence/playfulness (strong power/freedom incentives), whereas the preference of introverts for signals of loss and risk (harm avoidance) inclines them to express follower and dependency relations in association with greater social insecurity/submissiveness (strong comfort/safety incentives). Ultimately, since most dogs possess both extraverted and introverted traits, the coping styles, social roles, and personality characteristics that they express are highly flexible and tend to shift toward a centrist position under the influence of an adaptive coping style and constructive attunement dynamics. Under the influence of a reactive coping style and misattunement, though, extraversion and introversion become increasing unstable and extreme, with unstable extraverts becoming increasingly exploitive, intrusive, and impulsive, and unstable introverts becoming increasing cautious, withdrawn, and reactive.

PLAY AND DRIVE

Play possesses unique qualities and capacities to mediate rewarding exchange via the activation of a wide assortment of drive-related behaviors educed and liberated from functional significance, including sundry sex-related exploratory activities, seeking and exploratory behavior (object play), social exchanges (flirting, i.e., playful fleeing and fighting), and prey-predator interactions (stalking, chasing, body blocking, and grabbing). Play engenders a sense of empowering confidence that imbues the nervous system and body with a tonic balance of vigor and euphoric feelings of well-being or joy. Play is suspected to promote significant adaptogenic influences over critical neuropeptide and neurotransmitter systems that mediate autonomic attunement and antistress functions (see *Play and Autonomic Attunement* in Chapter 8).

As a specialized modal activity, play allows dogs to access various drive and motor programs and arousal systems but without activating the emotional command and hypothalamic effector systems that normally motivate these drives in earnest. The sum of the foregoing characteristics and neurobiological evidence suggests that play is probably integrated into a far-reaching network of neuronal pathways and attunement nodes that are orchestrated at an executive level (Vanderschuren et al., 1997). A reasonable candidate site of executive control is the dorsolateral PFC, a cortical area that appears to mediate the organization of proactive coping strategies in response to conflict. Some interesting work with juvenile rats has found that 30 minutes of rough-and-tumble play elevates brain-derived neurotrophic factor (BDNF) transcription in the dorsolateral frontal cortex and the amygdala (Gordon et al., 2003). This finding supports the idea that repeated play bouts may exert profound neurodevelopmental effects on executive function and lasting epigenetic influences on a dog's ability to cope with conflict (see *Cortical and Subcortical Comparator Functions and Adaptation*).

A prefrontal localization is consistent with the diverse anticonflict and attunement capacities that play appears to coordinate via an active appreciation of the attentional and emotional state of the play partner (see Horowitz, 2002). To sustain playful interaction, dogs must learn to limit exploitive excesses and to avoid causing play partners pain or fear. These various demands encourage dogs to play fairly and to reciprocally adjust to the play partner's needs, thereby promoting empathy for the sake of harmonious exchange. The distinctive reward features of play probably depend on play partners possessing the ability to regulate play exchanges in accord with a principle of fairness (see *Fair Play, Emergent Social Codes, and Cynopraxis* in Chapter 8). The autonomic and behavioral flexibility of play is likely to contribute an increased confidence and tolerance for unexpected social events. Play arousal is antagonistic to most aversive emotional states, providing a natural antidote against social anxiety, irritability/intolerance, and depression. During cynopraxic training, control modules and routines are brought under the modal control of play incentives. The harmony and fluid rhythms of play exchange are consistent with the integration of autonomic

attunement nodes that promote increasing attraction, attachment, and confidence as social familiarity and play skills develop. Play behavior appears to attune people and dogs to sustained cooperative exchange. The invigorated mutual attention and social engagement, harmonious modal shifting, choreographed proxemics, and mutual appreciation and joy give play exchanges an interactive form and beauty.

Fair Play and the Golden Rule

There is an inherent unfairness in the relative freedom of a trainer and a dog to initiate purposive exchanges and to control the dispensation of rewards—a disparity that requires a novel cynopraxic solution whereby the trainer's advantage is subordinated to the adaptive interests of the dog. Cynopraxic bond and life-experience imperatives are achieved in various ways, but ultimately all training and therapy activities are subordinated to enhancing a dog's ability to engage others in competent social exchange conducive to affection, play, and trust. People and dogs naturally derive significant hedonic value from play and tend to form lasting attachments as the result of social exchanges that entice and sustain playful interaction. Play is incompatible with social aversion, mistrust, and QOL deficiencies, while helping to promote social competence, confidence, and trust; in short, play is the expressive actualization of power. Play activities help to shape optimistic expectancies and improve a dog's ability to cope proactively with social uncertainty. In situations where playfulness is lacking, cynopraxic counseling and therapy efforts are energetically focused on enlivening playful dynamics between the family and the dog, placing the highest priority on enabling the family and the dog to engage in safe play. Working under the assumption that the most important reason to keep dogs is to enjoy their companionship, cynopraxic therapy and training canalize affectionate playfulness toward the attainment of interactive harmony, mutual appreciation, and joy. Regardless of a trainer's orientation, the training process is only truly humane and meaningful to the extent that it succeeds in establishing an affectionate and playful coexistence.

The prohibitions against competitive play that are frequently espoused in the popular dog literature are tailor-made to promote problems. The notion that play (e.g., tug games and roughhousing) promotes aggression is extremely misleading and destructive. In fact, play appears to enhance a dog's ability to cope proactively with conflict situations and unexpected changes that might otherwise result in more serious reactive contests. Players take and give advantage to optimize the reward intrinsic to play. To sustain such play activities, they must be sensitive to one another's needs and play fairly. In the process, dogs learn the *golden rule*: do as one wishes done in return. The leader is not distinguished by possessive irritability and a short-fuse temper that flares into rage at any provocation. A leader's status is measured by the amount of power and freedom he or she has to integrate playful exchanges with others—a prerequisite for integrating cohort relationships, guiding cooperative projects, and performing successful courtship rituals.

Dogs with good play skills exemplify the golden rule in the active and careful way they avoid violating the social code around the rights of first possession, apparently with some expectation that other dogs do the same in turn (see *Fair Play, Emergent Social Codes, and Cynopraxis* in Chapter 8). The code is respected regardless of the other dog's ability or willingness to defend the object in its possession. Leader-type dogs will even refuse direct countermands prompting them to take objects in violation of the code. When in possession of a valued object, however, these same dogs defend the code by a variety of strategies, often by stiffening over the object, which is an action that might also be interpreted in terms of the golden algorithm; that is, the stiffening may be intended to cause the other to hesitate or stop. If necessary, an expression of default dominance consisting of a startling growl-bark or fang whack may be used to defend the code, often followed by the dog shifting away with the object or taking it off to another location. Of course, such

dogs can deliver a vigorous defense against persistent intruders, if need be. A similar pattern of code-regulated behavior and default dominance may be shown around food and other highly valued resources, thereby exercising significant control over conflict-related tensions. The increased willingness of dogs to share valued objects and toys with people probably stems from the greater likelihood of people giving things to the dogs. Again, following the golden rule, giving to a dog is reciprocated by increased tolerance and capacity for sharing by the dog, perhaps fostering human-dog codes and attunement dynamics around shared comfort objects and resources that reduce the risk of conflict. In contrast, people that do not give but instead take, deprive, restrain, and threaten dogs may mobilize a pattern of exploitive and autoprotective dynamics in those dogs. The golden rule provides a useful social algorithm for guiding exchanges conducive to sharing, attuning dogs toward fair exchange and helping to decipher intent guiding canine social behavior.

For the average dog, the benefits of play for mediating social harmony and mutual enjoyment far outweigh any risks incurred by the activity. The common dire warnings and prohibitions against inhibitory training, tug games, and other social play activities often have the effect of *self-fulfilling prophecies*. By following the prohibitions against play, the very problems that an owner sought to avoid are actually facilitated. Many new dog owners hoping to calm an excitable puppy or reduce excessive mouthing or biting fall headlong for this idea. These sorts of arbitrary rules and prohibitions usually need to be imposed on other family members with considerable pressure, since the style of interaction required of them will likely feel stymied and unnatural, perhaps causing them to gradually withdraw their interest from the newcomer altogether. The loss of playful exchange is a tremendous sacrifice for everyone. Puppies and dogs appear to be attuned to play as a way to enjoy and become familiar with people and other dogs. The failure to engage in social play essentially denies a dog access to the interaction needed to integrate the relations required to become a full member of the household.

Note: The normal partition preventing play fighting and competition, roughhousing, and tug games from escalating into aggression in earnest may breakdown in certain dogs, especially certain fighting and guard-type breeds. Such dogs may be preemptively biased to respond to increased competitive arousal and excitement by shifting from a play mode into an attack mode. These dogs can be extremely dangerous for naive people to handle. In addition, nervous and reactive dogs can be dangerous when efforts are made to provoke them into play.

NEURAL COMPARATOR SYSTEMS

Preattentive Sensory Processing

Adaptive orienting behavior is mediated by spontaneous and search eye movements in response to auditory and visual stimuli. Spontaneous saccadic eye movements turn the visual apparatus toward the source of stimulus change in anticipation of an orienting response. These reflexive eye movements help to maintain a audiovisual interface with the immediate surroundings, enabling dogs to represent and map significant changes taking place in the immediate surroundings. Saccadic eye movements are associated with the target-arc response that precedes an orienting response. The target-arc response and saccadic eye movements are functionally associated with a complex network of interconnections between the PFC, superior colliculus (SC), limbic system, and brainstem. The encoding and representation of multimodal input into oculocentric sensory maps at the level of the SC has many implications for understanding how rapid adjustments to sudden change and novelty are perceived and integrated into adaptive and reactive preparatory adjustments. In addition to providing an audiovisual spatial representation mapping encoded sensory input, the SC via interconnectivity with cortical and limbic processing is intimately involved in expectant and preemptive processing of an emotional nature that affects how novelty and change are interpreted. The

detection and processing of change having potential significance appears to be mediated by preattentive interconnectivity between the SC, amygdala, PFC, basal ganglia, and brainstem, which rapidly process incoming sensory information. As a result, sensory processing may acquire a preemptive significance or lack thereof depending on a dog's history of exposure to aversive and attractive motivational events (Carretie et al., 2001; Ikeda and Hikosaka, 2003). As such, the emotional significance of reward and punishment appears to have a far-reaching influence on the preattentive and preemptive organization of perception, cognition, mood, and modal activity. For example, reward-mediated interconnectivity between the SC, PFC, and basal ganglia appears to bias orienting responses in a positive direction, whereas aversive emotional experiences activating preattentive networks between the SC, PFC, amygdala appears to promote a negativity bias (anticipatory anxiety) toward novelty and unexpected events (uncertainty). In addition, the SC may encode template information relevant to the detection of species-typical threats and has direct access to defensive centers organized at the level of the central nucleus of the amygdala, hypothalamus, periaqueductal gray (PAG), and basal ganglia that generates automatic and rapid-onset fear modules at the earliest stage of sensory processing and gating (see Öhman and Mineka, 2001).

The relative ability of an unexpected event to produce an orienting response depends on its conspicuousness, its phylogenetic significance, or its relevance to an ongoing project or venture. The detection of an inconsistency or mismatch in the flow of sensory data is cross-associated with the concurrent sensory input from other modalities contributing to the content of sensory maps represented at the level of the SC (e.g., sight, hearing, touch, and balance). The coordinated processing of preattentive sensory information deemed significant is tagged with hedonic value, resulting in appropriate emotional and autonomic arousal to promote attentional focus or intensification, as needed to guide adaptive actions. On the other hand, sensory events that are sufficiently conspicuous or salient to prompt an orienting response but lack relevance with respect to control incentives are gradually gated out by habituation and ignored by means of active inhibition associated with selective attention. In addition, the repeated exposure to a highly salient stimulus that attracts attention but without significant consequence will cause the stimulus to merge gradually into the background and prevent future associations from forming via latent inhibition (Dess and Overmier, 1989). Latent inhibition appears to cause dogs to actively ignore the event via inhibitory processing at the level of the PFC and SC, a stimulus biasing influence in the direction of irrelevance that must be unlearned for it to form significating associations that are relevant to a dog's control interests. If such a stimulus is repeatedly paired with some significant future event, it will gradually acquire prediction-control significance; however, the associative link between the two events may be more readily dissolved if the contingency between the events is discontinued than would be the case if the stimulus had never been previously presented independently of significance. Similarly, stimuli acquiring attractive or aversive significance resist change or conversion in the direction of an opposite hedonic valence or accepting new associative linkages with events of contrary motivational significance. Conditioned aversive and attractive stimuli acquired in association with first impressions at an early age may leave relatively permanent positive or negative biases that can be rapidly reinstated and guide behavioral output despite intensive counterconditioning or extinction efforts. Exposure and habituation to a broad assortment of uneventful environmental stimuli may reduce the risk of undesirable positive and negative biases that contribute to inappropriate appetites and aversive reactivity later in life via the shielding effects of latent inhibition.

Detecting and Processing Prediction Error

Neurobiological research indicates that reward, motivation, and mood are strongly modulated by mesolimbic and mesocortical

dopamine (DA) activity. Dopamine neurons located in the ventral tegmental area (VTA) show an increased firing rate when putative rewards occur unexpectedly or when such events exceed a dog's expectations. In contrast, DA neuron activity remains unchanged when an anticipated event matches a dog's expectations; when an anticipated event is less than expected or omitted, however, the firing rate is decreased (Schultz, 1998; Schultz and Dickinson, 2000). The VTA projects to the nucleus accumbens and forms a network of connectivity with the PFC, the amygdala, and various subcortical networks that perform comparator and valuative functions that enable dogs to interpret the motivational significance of novel and anticipated events and to adjust behavior accordingly, with cholinergic neurotransmission likely playing a prominent modulatory role (see Miranda et al., 2000; Giovannini et al., 2001; Kobayashi and Isa, 2002; McIntyre et al., 2003; Wu et al., 2004). The expectancy-comparator model proposes that prediction-control expectancies, calibrated establishing operations, and goal-directed actions are organized into control-expectancy modules and adaptive modal strategies. Control-expectancy modules and modal strategies are shaped by positive and negative prediction error into adaptive adjustments with the goal of optimizing instrumental control over significant motivational events (see *Prediction and Control Expectancies* in Chapter 1).

In the case of classical conditioning, when prediction mismatches occur, error signals mediate the recalibration of emotional establishing operations by selectively exciting or inhibiting relevant emotional command systems (valuative modulation), thereby increasing or decreasing motivational incentives and adjusting arousal to match the behavioral needs of the situation. Hypothetically, when control-expectancy mismatches occur, error signals are relayed along comparator loops and interconnecting pathways that mediate valuative changes coordinated with the recalibration of emotional establishing operations, thereby refining the control-expectancy module and modulating state arousal and action readiness to reflect the new information.

Prominent neural substrates and circuits hypothesized to perform this information-integrating process include plastic networks between the following:

Basolateral amygdala: a central hub coordinating the evaluation and attribution of emotional significance to novel and conditioned attractive and aversive motivational stimuli

Bed nucleus of the stria terminalis (BSNT): an extension of amygdala playing an important role in the mediation of seeking incentives, emotion, and vigilance

Ventral tegmental area (VTA): the source of the mesocortical DA pathway projecting to the PFC and activated by the central amygdala in response to psychological stressors

Nucleus accumbens: the mesolimbic DA reward area that plays a significant role in the coordination of incentive and hedonic value attributed to the gain and loss of reward objects

Pedunoculopontine tegmental nucleus (PPTN): the origin of cholinergic neurons responsive to prediction error/novelty and serving to modulate mesolimbic DA neurons mediating reward

Superior colliculus (SC): organizes multimodal sensory maps of the surroundings and orienting response

Lateral hypothalamus: contains hypocretin/orexin cells that promote arousal and alertness via complex interactions with cortical and limbic reward networks, autonomic effector systems, and feed-forward programming of serotonin and norepinephrine release associated with waking states

Basal forebrain: the origin of cholinergic networks modulating awareness and attentional response, hesitation, and increased exploratory activity in response to novelty and surprise

The PFC and the anterior cingulate area coordinate activity in these various limbic and subcortical systems while promoting selective attention and impulse control and organizing flexible control-expectancy modules and rou-

tines (see Schoenbaum and Setlow, 2001; Cardinal et al., 2002).

Attention, Impulse Control, and Processing Prediction Error

The executive selective attention and impulse-control functions of the PFC are largely dedicated to inhibition, but the PFC also mediates excitatory processing related to cortical reward via glutaminergic pathways, including excitatory input from the amygdala, information relevant to conditioned reinforcement in association with the control of aversive and attractive motivational incentives. Prefrontal and amygdalar-glutaminergic pathways also project to the nucleus accumbens and the VTA, areas of the brain that are strongly involved in mediation of reward (see *Prediction and Control Expectancies* in Chapter 1). Among the inhibitory effects of the PFC, the gating out of irrelevant or insignificant stimuli, as described in the previous section, are critical functions necessary to promote selective attention. In addition to selective attention, the PFC narrows response possibilities down to a single best bet based on ongoing control incentives, prediction-control expectancies, and emotional establishing operations. The PFC inhibits actions that are unlikely to succeed and disinhibits actions that are more likely to succeed, while contributing to the activation of active modal strategies via the surprise associated with outcomes. As such, the PFC appears to modulate behavioral output and emotional arousal through the exertion of tonic inhibition and phasic inhibition or disinhibition and the excitatory influence of reward. When instrumental behavior results in outcomes that are better than expected, the mismatch or *positive prediction error* results in phasic disinhibition and elation via excitatory inputs and outputs to reward centers. Conversely, if the behavior produces outcomes worse than expected, the mismatch or *negative prediction error* results in phasic inhibition and disappointment. When functioning under optimal conditions, tonic disinhibition promotes calming and mood states conducive to comfort and safety via the cumulative effects of somatic reward, whereas phasic disinhibition and excitation result in cortical reward and increased exploratory activity and inquisitiveness (active modal strategies), and phasic and tonic inhibition results in hesitation and delay (passive modal strategies). Under adverse conditions, excessive cortical inhibition may cause numerous disturbances of affect, motivation, and attention (hypervigilance) associated with inescapable loss and risk—disturbances that affect voluntary initiative. Disturbances affecting excitatory prefrontal reward systems or loss of appropriate inhibitory and disinhibitory modulation of reward-related behavior may play a significant role in the expression of exploitive novelty-seeking behavior and impulsivity, on the one hand, or incompetent power-seeking behavior, on the other (Van Erp and Miczek, 2000).

An important goal of cynopraxic therapy is to restore functional executive capacity to selective attention and impulse-control functions and to enliven spontaneity and playfulness—the result of a harmonious balance of somatic reward and cortical reward. A foundation of inhibitory control afforded by basic training provides an indispensable anchor for controlling reactive adjustments via the modulatory effects of prediction-control expectancies and provides reactive dogs with the autoregulation necessary to integrate an adaptive coping style and a repertoire of effective behavior. Establishing a reliable repertoire of basic modules and routines (e.g., formal heeling and automatic sit, controlled walking and quick sit, slack-leash walking, and reliable sit-stay and down-stay) is of tremendous value, both as a platform for behavior modification and for the intrinsic calming effects and enhanced social attraction that such training produces.

Cortical and Subcortical Comparator Functions and Adaptation

The selective attention and impulse control mediated and refined by goal-oriented prediction-control expectancies and emotional establishing operations are organized at the level of the PFC; in particular, orbital and medial PFC networks appear to play a crucial

role in governing control-expectancy modules and modulating shifts in attention and motivational direction (Öngür and Price, 2000), as needed to maintain purposive focus and to optimize control efforts (see *Cortical and Subcortical Comparator Functions and Adaptation*). Cortical reward and elation induced by the detection of positive prediction error serve to mobilize active modal strategies vectored on the search for additional opportunity. Reward arousal appears to be constrained by opponent processing, whereby the energy used to represent and experience reward is countered by an opposing *antireward* that restores homeostasis. Conflict monitoring and the detection of negative prediction error also set limits on reward-seeking activities. The anterior cingulate cortex (ACC) is hypothesized to play a key role in the monitoring and encoding of error signals (conflict) occurring in the context of instrumental projects and ventures. Conflict monitoring may be an important way for dogs to obtain control-relevant information not otherwise available. The detection of negative prediction error by the ACC results in motor inhibition and increased activity at the level of the dorsolateral PFC (DLPFC), where refinements to the control module may be integrated (MacDonald et al., 2000; Kerns et al., 2004). Consequently, in addition to monitoring control expectancies for action error or conflict, the ACC probably plays a central role in the mediation of passive modal strategies organized to minimize risk and loss (i.e., calculated hesitation, ritualization, and avoidance).

The conflict-monitoring and inhibitory functions performed by the ACC appear to divert executive attention to error (Luks et al., 2002), perhaps with the goal of "training" the executive PFC, as the egocentric object of emotional pain and distress, to avoid future similar adjustments to conflict. Conflict avoidance is likely a central contribution of the PFC to the integration of an adaptive coping style. In addition, the DLPFC appears to mediate an active interface that anticipates interactive conflict and selects response options that serve to resolve conflict proactively (Badre and Wagner, 2004). With the integration of reliable control modules, ACC error and conflict signals should decrease as executive attention and impulse-control capacities become increasingly competent (see Milham et al., 2003). In contrast to the proactive skills exhibited by dogs operating in accord with an adaptive coping style, reactive dogs treat attractive and aversive motivational stimuli in a highly impulsive manner. The pattern of reactive behavior shown by such dogs depends on their individual differences and specific motivational incentives, variably involving intrusive exploitation, despotic control efforts, social avoidance, or reactive inhibition (helplessness). These cognitive and behavioral changes are consistent with the nervous, exploitative, and autoprotective behaviors shown as the result of a *reactive coping style*.

The ACC is also a locus of interest with respect to the etiology of compulsive behaviors (Ursu et al., 2003; Van Veen and Carter, 2002). Whereas the PFC appears normally to integrate response error and conflict-related information in the process of modifying the control module, in the case of compulsive behavior the diversion of attentional resources for conflict monitoring may become dysfunctional, operating with a high degree of autonomy from the executive refinement of control modules. The increased conflict monitoring and behavioral inhibition mediated by the ACC may impair a dog's ability to vary behavior in response to executive adjustment signals. Whereas increased ACC activity appears to promote compulsive behavior, decreased ACC activity may facilitate impulsive behavior and inappropriate explosive adjustments in response to threats or challenges perceived to lack controllability. The ACC is also nicely positioned to monitor subcortical emotional signals arising in association with conflict (i.e., anxiety, frustration, resentment, worry, and despair) and increased autonomic arousal (Eisenberger et al., 2003). As such, the ACC appears to play a prominent role in the mediation of the reactive coping style emerging within the introversion dimension associated with persistent social ambivalence and entrapment dynamics. In contrast to the central role of the ACC for monitoring and coping with social conflict

and aversive state changes (emotional pain) mediated by autonomic state changes (Thayer and Lane, 2000), the DLPFC appears to actively counteract and prevent aversive state changes associated with social ambivalence and distress (Badre and Wagner, 2004) by heading off conflict by means of fair exchange, compromise, and cooperation. Decreased activity in the PFC may significantly impair a dog's capacity to maintain the flexible interface of autonomic attunement needed to regulate preparatory arousal in support of nonconflictive exchange.

Phylogenetic Survival Modes

According to cynopraxic theory, the cognitive and motivational changes occurring in response to conditions of plenty (favorable) and activity success versus conditions of adversity (unfavorable) and activity failure appear to mediate the expression of different phylogenetic survival modes (PSMs). In general, favorable conditions promote a coordinated *modal phase shift* consisting of cognitive and motivational changes conducive to social extraversion, power, expansion, elation, and well-being, whereas unfavorable conditions result in a coordinated cognitive and motivational shift in an opposite direction conducive to social withdrawal, inhibition and passivity, anxiety, irritability, intolerance, and autoprotective reactivity. Adaptation to persistent stressors may alter a dog's ability to shift flexibly in or out of modes. An inability to produce modal shifts conducive to autonomic attunement may occur as the result of the accumulated physiological and state changes or *allostatic load* acquired in the process of coping with chronic stressors that gradually impede rather than support adaptation (see *Survival Modes and Allostasis* in Chapter 8).

Survival Modes and Adaptation

PSMs exert overarching influences on the emergence of adaptive and maladaptive behavior by shifting motivational pressures, preferences, and priorities. Evidence for the existence of a switch activating PSMs in response to changing environmental conditions and metabolic pressures has been observed in the sedentary and nomadic behavior of male nonterritorial tree lizards (Knapp et al., 2003). Unlike aggressive counterparts who remain true to a territory, nonterritorial males are variably site-faithful or nomadic rovers, depending on environmental conditions. During harsh years of reduced rainfall the nonterritorial males tend to rove, whereas during more favorable years of increased rainfall they tend to stay put. Both male territorial and nonterritorial tree lizards show increased corticosterone levels during harsh years, but only nonterritorial males exhibit reduced testosterone levels. These two behavioral phenotypes appear to be differentiated by a polymorphism that includes a stress-sensitive switch that toggles on PSMs that affect aggression levels, territoriality, and reproductive tactics. During unfavorable years, elevated corticosterone levels and reduced testosterone appear to combine to toggle on a dispersal mode facilitating nomadic roving. However, during more favorable years in which corticosterone levels are low and testosterone high, the modal switch toggles on a sedentary mode conducive to site-faithful behavior.

Among laboratory rodents, the loss of control associated with restraint stress (defeat) or exposure to situations perceived as unfamiliar has been shown to affect agonistic and affiliative thresholds differentially in male and female rats. Female rats exposed to a single 30-minute period of restraint stress show little change in aggressive behavior when tested 24 hours later (Albonetti and Farabollini, 1995). However, if this same strain is exposed to novelty or novelty with restraint stress, the rats show significant change in both agonistic and affiliative behavior. Exposure to novelty alone appears to reduce agonistic behavior selectively while leaving affiliative behavior and allogrooming unaffected, whereas novelty plus restraint simultaneously increases both social agonism and affiliative behavior. The simultaneous activation of both agonistic and affiliative modes may reflect a general increase in autonomic arousal resulting in increased behavioral output in an effort to cope with chang-

ing (novel) social and environmental circumstances, improving the rat's ability to compete, on the one hand, and to engage in conciliatory behaviors, on the other. Interestingly, a factor analysis revealed that exposure to novelty alone not only decreased the frequency of aggressive behavior but also modified the way it was organized. Whereas controls showed two distinct factors partitioning offensive and defensive aggression, the rats exposed to novelty showed only one factor, suggesting that reactive thresholds controlling active and passive defensive reactions had been significantly altered by exposure to the treatment, perhaps enabling stressed rats to cope more effectively with environmental uncertainty.

Evidence consistent with survival-mode hypothesis has been reported in dogs and monkeys (see *Diet Change and the Integrate-or-Disperse Hypothesis* in Chapter 7). In the case of dogs, upgrading to a high-quality diet containing increased levels of fat and protein may either have a calming effect or increase reactivity toward novelty, depending on the presence or absence of social enrichment. Hennessy and colleagues (2002) found that dogs fed enhanced diets showed fewer signs of reactive arousal in response to novelty and startle, but only if they also received supplemental social interaction and training. Dogs receiving the fat- and protein-enhanced diet without social enrichment showed an opposite trend toward increased signs of anxious arousal. Two other groups of dogs were fed a diet containing significantly less fat and protein with and without social enrichment. In contrast to the beneficial effects of increased social interaction and training in the case of dogs fed the enhanced diet, dogs fed the diet containing less fat and protein showed more signs of anxious arousal in comparison to dogs not receiving social enrichment. Among cynomolgus macaques, Kaplan and colleagues (1996) showed that monkeys fed a high-fat diet were less aggressive and showed more affiliative behavior than monkeys fed a low-fat diet—changes linked to reduced serotonin turnover (Kaplan et al., 1994) (see *Fat, Cholesterol, Fatty Acids, and Impulsive Aggression* in Chapter 7).

Survival Modes, Neuropeptides, and Heterochrony

A comparison of genes expressed in the brain tissue of wolves, coyotes, and dogs has revealed that the most substantial genetic differences between domestic dogs and related wild canids are localized within the canine hypothalamus, with a high proportion of hypothalamic genes having been downregulated (Saetre et al., 2004). The study also found that gene expression in the frontal lobes reflected anticipated evolutionary distances, with dogs and wolves showing a closer genetic relatedness than exhibited by the coyotes to either. The third area examined, the amygdala, also showed some interspecific genetic variation, but clearly the hypothalamus appears to have undergone the most significant evolutionary remodeling as the result of domestication. In addition, several peptide systems have undergone significant change, including neuropeptide Y (NPY) and calcitonin-related polypeptide B, both playing important roles in energy homeostasis and appetitive behavior. NPY neurons are localized in the arcuate nucleus of the hypothalamus from where NPY fibers project widely to different areas of the brain. The hypothalamus regulates basic biological (e.g., energy homeostasis) and motivational functions and plays a key role in the coordinated release of numerous bioregulatory peptides in response to adaptive pressures. These ancient peptide systems bridge the brain-body gap, playing profoundly influential roles in the physiological processes associated with metabolism, thermogenesis and thermal regulation, visceral functions, growth, and reproductive activities.

In comparison to wolves and coyotes, dogs show a downregulation of the neuropeptide in the hypothalamus and an upregulation of NPY receptors expressed in the amygdala. NPY receptors in the basolateral nucleus of the amygdala appear to exert potent anxiolytic and antistress effects by dampening the activity of co-localized corticotropin-releasing factor (CRF) receptors (Sajdk et al., 2004). NPY has also been shown to regulate the release of oxytocin and vasopressin by the posterior pituitary (Sheikh et al., 1998), as well as exert modulatory effects on hypothalamic-pitu-

itary-adrenal (HPA) activity in dogs (Inoue et al., 1989; Miura et al., 1992). During sympathetic arousal, NPY release appears to mediate a pronounced inhibition of vagal tone by binding to acetylcholine receptors expressed on parasympathetic nerve endings (Rios et al., 1996). In addition to modulating stress reactions, NPY interacts with orexin to promote feeding behavior. Orexin is a neuropeptide believed to play a prominent role in energy homeostasis and alertness. Low levels of circulating leptin, a peptide produced by adipose cells that monitor energy reserves, stimulate NPY neurons to increase feeding behavior (Jéquier, 2002), while at the same time resetting the hypothalamic-pituitary-thyroid (HPT) axis in the direction of energy conservation and hypothyroidism (Fekete et al., 2001 and 2002). Circulating leptin levels vary in response to fasting and dietary state. Whereas NPY neurons are inhibited by high levels of circulating leptin, orexin neurons originating in the lateral hypothalamus project dense fibers to the arcuate nucleus that may stimulate NPY neurons to increase food intake independently of leptin signaling (Willie et al., 2001), perhaps suggesting a role of hedonic value dissociated from appetitive drive need.

The lateral hypothalamus receives strong projections from the orbitofrontal cortex (OFC), a prefrontal area believed to attribute hedonic value to food rewards (Rolls, 2000) and tactile stimulation. In addition to connectivity with the alertness-promoting cholinergic neurons of the basal forebrain, the lateral hypothalamus projects to the ventrolateral periaqueductal gray (vlPAG) (Öngür and Price, 2000), where it drives parasympathetic adjustments. The effector capacity of orexin and the wide distribution and interconnectivity of orexin receptors in key areas of the brain associated with reward, alertness, and energy homoeostasis (see Willie et al., 2001) suggest that the neuropeptide may play a pivotal role in scaling prediction error in terms of energy gain or loss as well as modulating arousal shifts in response to novelty and the subjective experience of reward. For example, orexin cells stimulate the dorsal raphe nucleus and the locus coeruleus via a feed-forward mechanism involving glutamatergic interneurons modulating the release of both serotonin (5-hydroxytryptamine or 5-HT) and norepinephrine (NE), which, in turn, exert an inhibitory feedback effect over orexin neurons (Li et al., 2002). The interconnectivity between the lateral hypothalamus and the orbitofrontal cortex and reward systems is consistent with the possibility that orexin stimulation of NPY neurons may play a role in sustaining modal seeking activity in response to goal-directed appetitive transactions yielding hedonic value.

The interconnectivity between the OFC, the lateral hypothalamus, and the vlPAG is also interesting with respect to canine narcolepsy, a disorder caused by a mutation of the hypocretin (orexin) receptor 2 gene (Lin et al., 1999). When excited by food or play, narcoleptic dogs are prone to cataleptic attacks stemming from deficit orexin neurotransmission (Fujiki et al., 2002). A network between the lateral hypothalamus, the dorsal raphe nucleus, and vlPAG may play a prominent role in this disorder, especially since the activation of the vlPAG results in tonic immobilization.

The upregulation of NPY receptors in the amygdala and the downregulation of the hypothalamus, as indicated by the finding of Saetre and colleagues (2004), are compatible with a reduced vulnerability for reactive arousal in response to social stressors, a functional change consistent with the differentiation of enhanced abilities to cope with stressful conflict situations. According to this hypothesis, corticohypothalamic nodes and networks interact reciprocally with various hypothalamic effector neurons to modulate allostatic drive and motivational state changes via direct enervation of sympathetic and parasympathetic ganglia as well as by releasing numerous peripheral hormones and neuroendocrine substances within the brain to coordinate metabolic changes conducive to attunement and energy homeostasis. In the wake of increasingly complex social relations and extended care/attachment relations associated with domestication, cortical executive networks appear to have evolved enhanced capacities to integrate sensory and motor

functions with hypothalamic effector systems to regulate drive functions in the direction of increasing sociability and tameness, bringing autonomic and metabolic processes under the enhanced efficiency and unification of centralized prediction-control mechanisms, enabling dogs to respond proactively in anticipation of events and thereby promoting adaptive optimization through social exchange.

In addition to reducing the excitability of hypothalamic effector neurons mediating flight-or-fight reactions, the reduction in predatory behavior by genetic alterations in limbic and hypothalamic nuclei governing prey-seeking drives (see Arons and Shoemaker, 1992) would have likely freed up enormous energy reserves, normally dedicated to the pursuit of predatory priorities, that perhaps turned to the pursuit of social and object play as a compensatory outlet or cooperative hunting for sport. Selection pressures for reduced predatory behavior and increased playfulness would probably have been a high priority with respect to adaptations enabling early dogs to interact safely with children. Similarly, the sexual pair bonding and extended parental behavior that wolves show toward their offspring are reduced in most dogs. Instead, dogs appear to sublimate pair bonding and parental caregiving into what Perin (1981) has described as "superabundant love," combining the sociosexual drives of the wolf mother and father into the playful affection and innocent attentiveness that transforms dogs into supernormal attachment objects (see *Supernormal Attachment Hypothesis* in Volume 2, Chapter 4). The various autonomic and interactive dimensions opened by the downregulation of hypothalamic effector systems mediating predatory and reactive behavior infuse the human-dog relationship with extraordinary capacity for social complexity and adaptability. The downregulation of hypothalamic effector mechanisms mediating flight-or-fight reactions in response to social approach should reduce the flight distance while simultaneously increasing social attraction, thereby elevating fear and aggression thresholds while lowering approach/exploratory thresholds. These behavioral changes are consistent with improved capacities for social engagement, increased tolerance for novelty, and reduced stress reactivity.

Physiological and behavioral support for this hypothesis has been reported among silver foxes selected for reduced fear and aggression toward humans. Foxes showing tameability and increased exploratory behavior have a significant reduction in plasma cortisol levels in comparison to reactive farm-bred counterparts (Trut, 2001). In additon to decreased HPA-axis tone, foxes selected for increased tameability show higher 5-HT levels in the midbrain and hypothalamus (Popova et al., 1991), suggesting that increased 5-HT levels may play a role in the inhibition of defensive behavior. Problematically, with respect to applying the fox model of domestication to dogs, the cortisol levels of wolf pups and adults do not vary appreciably from the baseline cortisol levels of dogs (Seal et al., 1975 and 1987). Further, among free-living wolves, there is no detectable correlation between cortisol levels and high rates of aggression and agonistic exchange (Sands and Creel, 2004). These findings appear at odds with those reported previously by McLeod and colleagues (1996), who described a significant correlation between glucocorticoid levels and rates of aggressive exchange between wolves. Sands and Creel suggest that a significant factor that may explain the heightened stress reactivity shown by captive wolves is related to the vulnerability of subordinates to unavoidable and severe attacks that are more common among captive wolf populations than among free-living groups. Finally, cortisol levels do not significantly differ between reactive and nonreactive dogs, until these two types of responders are exposed to fear-eliciting events and situations (Hydbring-Sandberg et al., 2004).

Other authors have emphasized the importance of the HPT axis and the hypothalamic-pituitary-gonadal (HPG) axis as playing a critical role in regulating developmental and physiological rates modulating neuronal excitation and inhibition. The extensive experimental work by Anderson (1941) and James (1941) was largely dedicated to investigating

the effects of thyroid hormone on the differentiation of behavioral and morphological types among dogs. They argued that temperament dimensions affecting relative excitability and adaptability might be driven by metabolic differences stemming from the level or quality of thyroid or pituitary secretion. They believed, for example, that the physical form, excitability, high activity levels, and alert typology of German shepherds was probably a reflection of an increased responsiveness to thyroid activity, whereas the physical morphology and behavior of basset hounds reflected a slowing physiological rate and reduced responsiveness and ability to acquire conditioned reflexes. To compare the effects of thyroid on behavior and development, numerous classical conditioning experiments were performed on German shepherd and basset hound crosses. The researchers found that they could alter the relative excitability of these intermediate types toward the hyperexcitability of German shepherds by altering thyroid and epinephrine levels, whereas ablation of the thyroid glands, gonads, and adrenal glands resulted in changes in the direction of the inhibited phenotype. These findings are consistent with heterochrony mediating the differentiation of breeds, whereby certain canine developmental rates are accelerated, resulting in peromorphosis (the German shepherd typology), whereas others are slowed down and result in paedomorphosis (the basset hound typology).

Dogs do appear to express individual differences with respect to the production and utilization of thyroid hormone. For example, a comparison of five breeds (beagle, sheltie, cocker spaniel, wirehaired fox terrier, and the basenji) showed that the basenji uses thyroxin at a higher rate than European breeds (Nunez et al., 1970). Whereas the basenji showed a mean thyroidal half-life of 3.3 days, dogs of a European ancestry showed a mean thyroidal half-life of 7 to 10 days. The monoestrous basenji is adapted to an equatorial environment and exhibits an annual breeding cycle timed to occur with the decreasing daylight that occurs around September or October (Scott et al., 1959), whereas the wolf is adapted to temperate climates and programmed to initiate reproductive activity as daylight increases in January or February. Nunez and colleagues speculate that the changes to the reproductive cycles of the basenji may be the result of a genetic alteration in thyroid functions. Among wolves, the reproductive cycle reportedly varies with latitude, occurring earlier in the year at lower latitudes (Seal et al., 1987). Interestingly, Cape hunting dogs shift the timing of reproductive cycles a full 6 months when moved from Southern Africa to Ireland (reported by Seal et al., 1987). In contrast to the basenji, the reproductive cycle of European breeds appears to operate in relative independence to seasonal light periods and the endocrine control mediated by the pineal gland. Dogs that are housed together with other dogs or that come into contact with wolves reportedly show evidence of synchronizing their estrus cycles with the estrus cycles of other females (Harrington and Asa, 2003); further, dogs are kept in close proximity with wolves appear to show evidence of increased reproductive photoperiodicity, coming into estrus in January–February and then again in August–September (Kreeger, 2003).

Hiestand (1989) has speculated that the previously discussed research of James and Anderson suggests the possibility that the neoteny hypothesized to distinguish dogs from wolves (see *Paedomorphosis* in Volume 1, Chapter 1) may be due to genetic alterations affecting the sensitivity of different dog breeds to the effects thyroid hormones—speculation consistent with the notion that early domestication may have resulted in significant changes affecting the pulsatile release and turnover of thyroid (Crockford, 2002). The pulsatile secretion of thyroid-releasing hormone (TRH) by the hypothalamus acts on the anterior pituitary to produce thyroid-stimulating hormone (TSH) and the release of thyroid into the bloodstream (Kooistra et al., 2000). Given the negative-feedback effects of circulating thyroid hormones on TRH and TSH activity, increased episodic production of TRH would likely promote hypothyroidism and elevated prolactin levels (Kaufman et al., 1985), a change in thyroid function consistent with the neoteny hypothesis.

However, somewhat problematic for the neoteny hypothesis are the results of chemistry studies of blood taken from wild-caught wolf pups (4 to 7 months) indicating that young wolves show a tendency toward lower thyroid (T4) concentrations in comparison to dogs (beagles) (Seal et al., 1975). Similar trends toward hypothyroidism have been shown in adult wolves. The thyroid levels of wolves undergo seasonal changes, with thyroxin (T4) levels increasing in the winter and decreasing in the summer (Seal et al., 1987).

Dogs appear to express varying degrees and types of developmental rate changes consistent with dissociated heterochrony. According to this hypothesis, dog breeds are not more or less neotenous but rather show evidence of selective developmental changes that delay (paedomorphosis) or accelerate (peromorphosis) the organization of various behavioral and physiological systems. Alterations in thyroid activity at different prenatal and postnatal periods may yield altered sensitivities to thyroid and mediate functional and morphological changes to the canine phenotype.

Strong evidence indicates that developmental changes in thyroid levels regulate the timing of the metamorphosis of tadpoles into frogs (Bentley, 1976). Evidence of similar thyroid-mediated effects on developmental rates among mammals is less secure, but some well-controlled investigations do indicate that the timing of developmental markers is altered in response to treatments that increase or decrease thyroid activity during prenatal and postnatal development. Maternal thyroid has been demonstrated to alter the expression of the neuroendocrine-specific protein (NSP) and a gene encoding the Oct-1 transcription factor in the cortex and limbic system of the rat brain (Dowling et al., 2000). NSP is believed to play a critical role in the differentiation of neuronal tissue via the modulatory influence of thyroid hormone. Animals exposed to increased fetal thyroid show lasting focal changes in NSP expression in the hippocampus that is enhanced by adult hypothyroidism, whereas Oct-1 expression in the cortex and hippocampus is suppressed in adulthood. Even relatively slight changes in maternal thyroid levels can lead to lasting changes affecting neural development and learning abilities (Colburn, 2004).

In addition to prenatal effects, neonatal hypothyroidism has been shown to exert profound ontogenetic effects over the regulation of genes that program the development of the brain and sensory abilities, including neuronal differentiation, cell migration, synaptogenesis, dendritic structure, and myelination. Thyroid hormone (T3) or triiodothyronine is instrumentally involved in the postnatal organization of 5-HT neural pathways that regulate the stress management system (see *Antistress Neurobiology, Maternal Care, and Coping Style in Chapter 8*). Alterations of thyroid activity can exert lasting impairments affecting the animal's ability to learn and to adapt (see Thompson and Potter, 2000). Recently, Yilmazer-Hanke and colleagues (2004) have shown that the induction of neonatal hyperthyroidism hastens the opening of eyes as well as producing morphological changes consistent with peromorphism (e.g., snout elongation). In addition, transient hyperthyroidism produced several key changes affecting amygdalar activity that continued into adulthood, including a reduction of CRF neurons in the central nucleus of the amygdala and an increase of NPY neurons in the basolateral complex, while increasing the density of tyrosine-hydrolase-positive fibers (indicative of DA transmission). These various amygdalar changes were found to exert various anti-anxiety effects consistent with increased adaptability and tameness. The presence of increased DA activity suggests that part of these changes might be due to sensitization of DA neurons in the VTA, a connection that may play a pivotal role in the process of attributing and updating the hedonic value of motivational stimuli (Baxter and Murray, 2002).

Developmentally, foxes selected for tameness show a steady trend toward increasing exploratory activity and fearlessness in response to novelty, whereas farm-bred foxes become increasingly fearful and inhibited in response to novelty (Belyaev et al., 1984/85). The eyes of tameable fox pups are completely opened sooner than are those of reactive farm-bred counterparts. Also, foxes selected

for tameness show a slightly earlier orienting response to sound. These changes accelerating the opening of the eyes and tendencies toward increased exploratory activity are consistent with the aforementioned effects produced by the administration of thyroid on developmental rates in rats (see Brosvic et al., 2002). Whether these alterations in timing affecting the emergence of fear-related behavior and sensory development among foxes selected for tameness is due to maternal thyroid changes is currently unknown, but the findings do raise a number of interesting questions for future research.

A dissociated heterochrony appears to affect the timing of sensory development and the eruption of teeth among coyotes, wolves, and dogs. Snow (1967), for example, found that coyotes opened their eyes, on average, at day 14, but the milk teeth of coyote pups can already be felt at day 10, 10 days before the canine incisors of dogs can be felt through the gums (Scott and Fuller, 1965). Mech (1970) observed that the front teeth of two wolf pups he raised emerged at day 15, whereas the eyes began to open at day 12 and were wide open by day 15. The developmental dissociation between the eruption of teeth and the opening of eyes in coyotes, wolves, and dogs is consistent with paedomorphosis affecting dentition but not sensory development, with the eyes of dogs opening, on average (with significant breed variation), around day 13 (Scott and Fuller, 1965). The early emergence of reproductive behavior among dogs may reflect an acceleration of developmental rates consistent with peromorphosis, whereas the extended playfulness of dogs may represent a change consistent with a paedomorphic delay affecting social and emotional development.

Since thyroid activity is sensitive to external temperature, with cold temperatures causing an elevation of circulating thyroid (Seal et al., 1987), wolf mothers gestating under cold climate conditions ought to produce more circulating thyroid hormone than mothers gestating under warmer conditions. Given the high degree of fetal responsiveness to maternal thyroid levels, it is reasonable to expect differences resulting from winter gestation and that these differences might affect the adaptability of offspring, with adults showing an increased sensitivity to thyroid levels, causing them to tend toward seasonal hypothyroidism. Hypothyroidism during summer months might enable wolves to conserve and store energy reserves in the form of fat, whereas hyperthyroidism in the winter would enable them to use these fat reserves to maintain thermal homeostasis.

These changes fit nicely with the genetic alterations of the amygdala and hypothalamus identified by Saetre and colleagues (2004) and the thyroid hypotheses posited by Hiestand (1989) and by Crockford (2002). Reduced hypothalamic NPY activity might result in periodic shifts toward hyperthyroidism coincident with critical prenatal and postnatal developmental periods that might result in adult changes inclining toward hypothyroidism via neural sensitization and enhanced negative feedback regulating thyroid release. These alterations in thyroid activity might also reduce the number of CRF neurons in the central nucleus (thereby reducing HPA-axis reactivity) while supporting connectivity between NPY interneurons in the basolateral complex with mesolimbic and orbitofrontal reward circuits projecting to the lateral hypothalamus, completing a feedforward loop involving orexin-mediated excitatory effects on NPY activity. According to this hypothesis, orexin neurons in the lateral hypothalamus may play a prominent role in the modulation of NPY neurons in the process of mediating hedonic value and a heightened state of alertness, action readiness, and increased exploratory activity, as discussed previously in this section. In addition, a network of neural activity of this sort is consistent with enhanced antistress capabilities, increased sociability, and adaptive optimization.

Survival Modes, Control Incentives, and Reward

The relatively small social and dietary QOL enhancements needed to mobilize mode changes suggest the involvement of conditioned associations, perhaps involving NPY regulated release of arginine vasopressin

(AVP) and oxytocin (Sheikh et al., 1998). Among rats, for example, food deprivation results in a persistent state of biological distress that elevates AVP activity, promotes adrenal hypertrophy, and mediates a twofold increase in NE turnover in brainstem (El Fazaa et al., 2000). Food- and water-deprived rats also show elevated glucocorticoid levels and a potentiated increase in catecholamine release in response to acute immobilization (Kiss et al., 1994). In contrast, the closely related neuropeptide, oxytocin, plays many complementary antistress and antiaggression roles by way of linkages among sucking, ingestion, tactile stimulation, social affiliation, and autonomic attunement antagonistic to the stress-mediating effects of AVP. These oxytocin effects are consistent with an important role in the activation of the social engagement system (SES) and the integration of secure attachments. AVP and oxytocin appear to modulate thresholds regulating autonomic tone and a dog's ability to obtain hedonic value from social, appetitive, and tactile exchanges while organizing an adaptive coping style (Ostrowski, 1998).

AVP is hypothesized to play a role in mediation of state changes underlying nervous attachments, irritability, and repulsion consistent with the loner-dispersal mode, whereas oxytocin promotes changes consistent with secure attachments, including the calming, comfort and safety, and pleasure derived from eating, petting, and warmth. According to this hypothesis, oxytocin may increase neural activity in pathways conducive to social engagement by lowering the excitation thresholds of neurons and circuits mediating increased parasympathetic tone and attributing positive hedonic value (attraction and calming) to social attention, appetitive rewards, and tactile stimulation. In contrast, AVP may route neural activity consistent with the loner-dispersal mode by lowering excitation threshold of neurons and circuits mediating sympathetic arousal and attributing negative hedonic value (aversion and agitation) to social attention, appetitive rewards, and tactile stimulation, thereby increasing social irritability, intolerance, and autoprotective behavior. Neuropeptide-mediated alterations of neuronal responsiveness to the hedonic value of social stimuli would serve a potentially beneficial function by limiting attachment behaviors to appropriate social partners. Consistent with such social functions, oxytocin and AVP play complex roles in the establishment of durable social memories (e.g., kin recognition) and affiliative bonds, as well as mediate potent states of social aversion and aggression toward unfamiliar conspecific intruders.

Although the survival mode is immensely influential, it does not dictate the behavior expressed by a dog but rather serves to modify behavior by altering the incentive and hedonic value of social exchange. According to the integrate-or-disperse hypothesis, the hedonic value of social exchange may shift depending on the survival-mode active at the time (see *Diet Change and the Integrate-or-Disperse Hypothesis* in Chapter 7). In particular, the hypothesis predicts that QOL enhancements in the absence of increased affiliative exchange promote anxiety and insecure attachments. A further prediction asserts that QOL diminishments made while increasing social interaction tend to promote dispersive tensions, which, if blocked, generate social ambivalence and entrapment dynamics. Consequently, persistent exposure to inescapable social situations that provide poor QOL resources (entrapment) but nevertheless make high demands on a dog for social contact, may amplify dispersive tensions and promote antipredatory and autoprotective adjustments in response to ambiguous signals. Accordingly, QOL changes may generate significant motivational changes promoting social integration or dispersion, depending on the availability of adaptive social options consonant with the activated survival mode.

The quality of social or place attachments exerts an immense effect on the hedonic value of transactions resulting in social and appetitive reward. For example, under circumstances perceived as secure, the contingent delivery of social attention, tactile stimulation, and play may produce positive hedonic value and state changes conducive to social attraction and integration. In contrast, under the influence of circumstances perceived as insecure or unsafe, the same social exchange will produce

aversive state changes conducive to reactive adjustments and social dispersion. The reward value of affectionate petting and hugging will greatly vary, depending on the survival mode active at the time of receiving it and the quality of attachment between the dog and the person giving it. Whereas petting and hugging or playful teasing may yield a high degree of positive hedonic value (e.g., calming and enjoyment) for a dog operating under the influence of autonomic attunement and secure attachments (social integration mode), the autonomic state changes and physiological alterations of neuronal substrates and target organs mediating the loner-dispersal mode may cause such playful and affectionate actions to yield a negative hedonic value (e.g., resentment and irritability), especially in the presence of a QOL diminishment.

Survival Modes, Energy Homeostasis, and Stress

During stressful arousal in anticipation of increased energy demands, complex physiological changes are orchestrated to protect or restore energy homeostasis. Thus, neuropeptide signals (principally CRF and AVP) converging on the pituitary modulate the release of adrenocorticotropic hormone (ACTH) into the bloodstream. ACTH stimulates the adrenal cortex to release glucocorticoids, thus activating numerous metabolic, anti-inflammatory, and cognitive-emotional changes conducive to adaptation and energy homeostasis. The size of this adaptation and denouement phase (allostasis) is followed by several key changes affecting flight-or-fight thresholds. The activation of the HPA axis and the release of adrenal glucocorticoids into the bloodstream promotes a state of positive energy balance (excess), whereas the activation of the HPT axis in response to severe stressors produces an energy deficit by increasing the metabolic rate (Horvath et al., 2004).

In addition to the varied caloric requirements needed by working dogs to maintain energy homeostasis, genetic peculiarities may influence a dog's capacity to anticipate and efficiently supply the changing energy requirements needed by the brain and body to support goal-directed behavior. The recent finding that a structure of genetic relatedness between different dog breeds collects principally around four clusters of genomic variation (Parker et al., 2004) raises the possibility that individuals belonging to these different genetic groups may express digestive and metabolic variations that require different nutritional support to achieve energy homeostasis. For example, Frank (1987) has reported preliminary evidence suggesting that Northern breeds (e.g., the malamute) may possess more efficient metabolic capacities than other dog breeds or wolves. The metabolic and nutritional requirements of breeds specialized for sprint racing and long-distance racing varies significantly. Whereas sled dogs appear to perform best when fed diets containing high fat (50%) and high protein (30%), greyhounds appear to perform best when fed diets containing more moderate levels of fat and protein (Hill, 1998). The groupings identified by Parker and colleagues may provide a valuable frame of reference for investigating nutritional differences and, if necessary, formulating canine diets compatible with the specific needs identified. According to this hypothesis, diverse breeds, such as the Bernese mountain dog, greyhound, and the Shiba Inu, have probably evolved very different nutritional requirements and metabolic capacities due to local customs and food availability. A mismatch between a dog's diet and its breed-specific and individual differences affecting metabolism may result in compensatory appetitive and motor efforts to achieve the requisite state of balance and metabolic repose.

A failure to achieve a state of metabolic comfort and energy homeostasis may mobilize disorganized striving and increased catecholamine activity via the activation of sympathetic-adrenomedullary (SAM) system. Whereas epinephrine appears to play a prominent role by mobilizing a rapid state of generalized arousal and increased glucose metabolism (McGuinness et al., 1997), NE appears to mediate lipid metabolism in preparation for sustained physical exertion (Connolly et al., 1991). In addition to promoting rapid preparatory thermogenic and visceral changes

serving to prime and mobilize the emergency system into a state of heightened arousal and readiness, the SAM system exerts excitatory cardiovascular and muscle-tone changes inclining dogs toward confrontation or retreat (see *Periaqueductal Gray and Autoprotective Adjustments to Social Stressors*). Verrier and Dickerson (1991) found that NE predominates the catecholamine flow evoked by anger in dogs. Among cats, different catecholamine proportions emerge, depending on the nature of psychological stressors presented (Stoddard et al., 1987). Among dogs, NE released at $ß_1$-adrenergic receptors appears to play a prominent role in mobilizing cardiovascular changes associated with acute anger states, with cardioselective $ß_1$-adrenergic antagonist, metoprolol-blunting T-wave alternans (TWA), a heart beat pattern reflecting cardiac instability that is evoked by anger and stress, not a secondary instability resulting from an elevated heart rate. This research suggests the possibility that TWA, perhaps in conjunction with heart-rate variability tests, may provide a useful marker for evaluating sympathovagal tone and canine aggressive propensities in response to anger-evoking stimulation (see *Heart-rate Variability* in Chapter 9). Interestingly, sympathectomized dogs (Brouha et al., 1936; Brouha and Nowak, 1939) or dogs under the influence of strong ß-adrenergic blockade (Roossien et al., 2000) show evidence of parasympathetic-driven cardiac accelerator effects conduced by vagal receptors, perhaps mediated by the combined action of acetylcholine and vasoactive intestinal peptide (VIP) (Roossien et al., 2000). Brouha and colleagues (1936) include a photograph of two dogs straining on leashes to fight, even though the sympathetic pathways of both dogs had been surgically disrupted. Despite severe sympathetic impairments, the dogs appeared to show normal running, jumping, playing, and active and passive defensive reactions, suggesting that sympathetic arousal systems are integrated into voluntary behavior at another level of neural organization.

Dogs cope with exchanges perceived as challenges or threats by increasing arousal, vigilance, and readiness—changes that are mediated by cortical and limbic signal converging on the hypothalamus. The activation of emotional systems involved in coping with psychological stressors and demands causes numerous endocrine changes that shift the body into a catabolic state in anticipation of energy outflow. As conflict is resolved, these catabolic processes are substituted by increased anabolic activity organized to conserve and restore energy reserves and to mediate energy conservation, bodily repair, and healing. By means of prior exchanges with others and the environment, predictive information is acquired that enables dogs to match adaptive control efforts with the energy resources needed to succeed. Under conditions of chronic interactive conflict, a state of persistent heightened arousal and *vigilance* (anxiety) may result in a chronic state of physiological stress affecting a dog's ability to competently utilize, produce, and conserve metabolic resources in a manner that promotes energy homeostasis and heath. In addition to the adverse stress effects of persistent anxiety, appetitive frustration promoting heightened arousal and *action readiness* may exert damaging effects on the body and behavior. For example, extinction procedures have been shown to increase HPA-axis activity. Several studies investigating the physiological effects of extinction have shown that rats and monkeys experience a significant rise in glucocorticoid release when exposed to appetitive extinction procedures. Although an increased frequency of reward results in a decrease of glucocorticoid activity during the acquisition phase of training, rewards that fall short of expectations result in increased glucocorticoid activity (Lyons et al., 2000), suggesting that circuits regulating the HPA axis are sensitive to positive and negative prediction error signals. During the extinction phase of a control module, the magnitude of change in HPA-axis activity is proportional to the value of the rewards obtained during the acquisition phase of training (Kawasaki and Iwasaki,1997). The increased active modal activity that often occurs during the initial extinction phase appears to be corticosterone-mediated, with adrenalectomy abolishing the extinction burst in rats (Thomas and Papini, 2001).

Circulating glucocorticoids enter the brain and interact there with mesolimbic dopamine

pathways, perhaps playing a facilitative role in the process of extinction by mediating the expression of active modal strategies in response to surprising nonreward, to borrow Papini's term (Papini, 2003). Instrumental extinction is an active learning process, whereby the animal preserves the general structure and sequential organization of a previously effective action pattern, while exploring and experimenting with the changed situation in an effort to restablish and optimize effective control (see Neuringer et al., 2001). Whereas the acute activation of the HPA system in response to the temporary loss of control over a previously controllable attractive or aversive event may augment adaptive capacities, chronic exposure to distressing frustration and anxiety in association with uncontrollable motivational events appears to gradually diminish the dog's ability to experience reward and to integrate an adaptive coping style. The net result of chronic stress is a reduction of purposive reward-seeking activity in combination with mood changes conducive to social withdrawal, anxiety, irritability, and incompetence. The widely held assumption that the activation of the HPA-axis is indicative of adverse stress is obviously flawed. The foregoing findings suggest that cortisol measures may not be a very useful stand-alone indicator of the dog's welfare status. In fact, a robust adrenal release of cortisol in response to the disconfirmation of expectant prediction-control efforts appears to actually facilitate behavioral changes conducive to adaptive optimization. Actually, one might better argue that diminished HPA-axis activity in response to the repeated disconfirmation of a previously reliable control module would be more indicative of disruptive stress and allostatic load than adaptive stability.

Dog breeds and individuals show significant differences in their ability to cope and adjust to adverse environmental circumstances. Hydbring-Sandberg and colleagues (2004) have reported that dogs showing low-auditory startle thresholds in response to gunshots exhibit a robust cortisol and progesterone response not shown by dogs exhibiting high-startle thresholds. The same loud-noise stimulation has little effect on the release of cortisol and progesterone in the latter, less sensitive group. Interestingly, the experimenters found that baseline measures (e.g., heart rate, hematocrit values, cortisol, progesterone, endorphin, and vasopressin) taken from fearful and fearless dogs did not significantly differ. The relative dependence of stress-related adjustments on the vagaries of individual difference raises significant questions concerning the objectivity of assumptions and generalization regarding the intrinsic stress potential of different classes of sensory stimuli. The blast of a shotgun for a hunting dog signals a very different chain of associative events than the blast produced by a firecracker thrown into the backyard. Similarly, careening down a snow-covered mountain on long fiberglass runners fastened to the feet would represent a robust and terrifying experience for a nonskier but be a source of pleasurable exhilaration for an expert skier. The key differences between stressors and nonstressors revolve around relative predictability, controllability, and familiarity, on the one hand, and the possession of appropriate skills and the confidence needed to use them effectively, on the other. The study draws into serious doubt the value of psychological stress studies that fail to separate dogs into test groups based on behavioral thresholds and temperament types.

Genetic Influences on Adaptive and Reactive Coping Styles

Dopamine Regulatory Polymorphisms and Reactive Behavioral Phenotypes

Complex interactions between hereditary influences and experience influence how dogs cope with adversity (loss of control). The way a dog responds to novelty and unexpected events appears to exert a profound stabilizing or destabilizing influence on its temperament and coping style. There are four general ways in which the dog responds to novelty and strangeness: fearlessly, conflictively, aggressively, and fearfully. A possible genetic factor affecting how dogs respond to novelty and unfamiliar persons or other dogs may be traceable to polymorphisms regulating the

expression of DA receptors, especially D_2 and D_4 subtypes (see *Neural and Physiological Substrates* in Volume 2, Chapter 5). Mice lacking the D_4-receptor gene show a significant reduction of exploratory behavior and increased approach-avoidance conflict toward novel objects in comparison to wild mice (Dulawa et al., 1999). The functional significance of D_4-receptor polymorphisms on temperament in humans is currently controversial and clouded with contradictory findings (Kluger et al., 2002). Whether D_4 polymorphisms adversely affect canine adaptive behavior is unknown, but some intriguing evidence is highly suggestive with regards to the possibility of such an effect. Niimi and colleagues (1999) have reported significant differences in the distribution of D_4 alleles in the genomes of the golden retriever and the Shiba inus. They have cautiously suggested that these genetic variations may contribute to some of the temperament differences exhibited by these two breeds. For example, the long D allele prominent in the Shiba inu may contribute to the breed's reputed territoriality and propensity for reactive excitability toward other dogs. The Shiba also appears to express variant D_4 alleles not found in the genome of other dog breeds thus far studied (e.g., beagle, sheltie, golden retriever) (Niimi et al., 2001), consistent with the breed's ancient origins and relatively close genetic relationship with the wolf (see Parker et al., 2004).

Another line of relevant research in dogs has investigated polymorphisms affecting the gene responsible for the production of catechol-O-methyltransferase (COMT) (Masuda 2004), an enzyme that metabolizes dopamine and norepinephrine (Tunbridge, 2004). The polymorphisms affecting the canine COMT gene are similar to those that have been identified in humans, suggesting that COMT may play a role in the elaboration of dopamine-related predispositions underlying certain adjustment problems. Tunbridge and colleagues (2004) have reported that the inhibition of COMT release at the level of the prefrontal cortex serves to enhance attention functions by increasing dopamine availability. Interestingly, the effects of COMT are only evident under conditions of increased arousal when increased prefrontal dopamine activity appears to facilitate flexible attention shifting. These findings are consistent with the hypothesis that polymorphisms affecting the COMT gene may contribute to selective attention and impulse control deficits associated with impulsive aggression. Too little or too much dopamine release in the PFC at times of increased arousal appear to be conducive to impulsive and reactive adjustments. These findings suggest the possibility that polymorphisms affecting the dopamine transporter gene might also contribute an adverse predisposing influence affecting the functional competency of executive functions.

Breed and Individual Difference and Reactive/Impulsive Behavior

Breed and individual differences affecting excitability, emotional reactivity (anger and fear thresholds), and cognitive organization (attention and impulse control) exert significant influences on how dogs cope with the conflictive exchange and emotional tensions generated by social ambivalence and entrapment (James, 1939; Sgoifo et al., 1996). Van Der Velden and colleagues (1976) described a pattern of impulsive CDA exhibited by a population of Bernese Mountain dogs in the Netherlands. Of 800 questionnaires sent to owners, 404 were returned and analyzed. The researchers found that not less than 20% of the owners reported that their dog had attacked family members intermittently with "blind aggressiveness" (404). The dogs that had threatened owners or delivered attacks were most often males (76%), whereas females were over represented in the group showing shyness and "unbalanced" temperaments only when away from their home territory. The attacks exhibited by the affected dogs were episodic and out of character with otherwise friendly behavior. Some of the dogs appeared insecure (shy and nervous) while others were reported to exhibit hypersexual behavior. The provoking stimulus was frequently a command or prohibition, even when given in a friendly and nonthreatening way. Some of the dogs responded to the least amount of restraint or force with "real panic"

(404). Often the owner was unable to identify an evoking stimulus triggering the attack. Dogs showing this behavior were reported as shy or avoidant as puppies, especially with respect to strangers. As puppies and adults, the dogs showed a "clear lack of communication" (404). The owners described a rutilant glow in the dog's eyes immediately before the attack took place. Attacks were directed against family members in circumstances consistent with a dominance-aggression interpretation. Interestingly, when rehomed aggressors only began to attack family members again after they had established social attachments with them. Since the attacks were described as resembling impulsive fits or seizures, a series of neurological tests [kindling and electroencephalogram (EEG)] were performed to exclude epilepsy. In addition, necropsies and microscopic examination of the brain tissue from 8 dogs found no evidence of pathology. Intracranial EEG recordings of 7 dogs presenting varying signs of reactivity, including a history of attack behavior, were taken by inserting electrodes bilaterally into the temporal and orbitofrontal cortex, the amygdala, and the hippocampus. The testing failed to reveal evidence of epileptic-like spontaneous activity. The authors stress the likely role of genetic factors in the etiology of the impulsive aggression exhibited by these dogs.

Other breeds, notably the cocker spaniel and English springer spaniel, have also attracted clinical and scientific interest stemming from similar presenting signs, often collectively described as dominance-related. Mugford (1984) found that English cocker spaniel dogs (N=50) with aggression problems, showed a highly uniform pattern of attacks directed exclusively against family members in association with moodiness and the defense of bones, food, and defended areas (e.g., under furniture). Aggressive propensities appeared to decrease when the dogs were in less familial surroundings. Male dogs delivered most attacks (68%), with males also showing more severe aggression than females. The eyes of attacking dogs changed color and the attack worsened as the result of physical punishment. Most dogs appeared confused and contrite after the attack. Mugford's data suggests that a linkage between temperament and coat color may exist in the English cocker spaniel, since 74% of the aggressors were red or golden in color, 20% were black, 6% were designated as other (e.g., parti-colored); a relationship later confirmed by Podberscek and Serpell (1996). The apparent reduced incidence of aggression in parti-colored English cocker spaniels is consistent with data collect by Belyaev and colleagues (Trut, 1999). Belyaev's group found that piebald pelage is highly correlated with tameness in foxes (see *The Silver Fox: A Possible Model of Domestication* in Volume 1, Chapter 1).

A similar pattern of dominance-like behavior has been reported to occur disproportionately among English springer spaniels. According to Reisner (1996), the English springer spaniel is the breed presenting most frequently for treatment of dominance-aggression problems. The results of a large questionnaire survey involving 1,053 springer owners (53.1%) indicate that 26.4% reported that their dog had bitten someone, which was often a family member or a person familiar to the dog (65.2%) (Reisner, 1996). Reisner reports that nearly half (48.4%) of these domestic aggressors had growled, snapped, or bitten in situations associated with dominance. In a sample of 53 cases involving springer spaniels diagnosed as dominance-related aggression, males presented twice as often as females (Reisner, 1993). Again, attacks were most common around food and prized objects, with dogs also showing aggression in response to punishment or when disturbed while resting or sleeping. Interestingly, with respect to a possible genetic defect, a statistic analysis of pedigree data revealed that a particular kennel and sire was highly associated with dogs showing the aggressive trait ($p=0.002$) (Reisner, 1996), suggesting the possibility of a popular sire effect (see *Prospects for the Future* in Volume 1, Chapter 1). The results of a similarly large survey of English cocker spaniel owners also found evidence of a combined genetic and behavioral influence, but then conclude that domestic attacks occurring suddenly and without apparent provocation are not of some separate

category (Podberscek and Serpell, 1996), but are "clearly associated with other symptoms of dominance-type aggression" (87) and therefore should be interpreted in terms of social dominance incentives. In addition to intrafamilial aggression, the authors found that a large percentage of the dogs showed extrafamiliar aggression, threatening or attacking persons visiting the home or strangers away from home. Allen and colleagues (1974) have described a sibling group of Alaskan malamutes that showed severe fighting and predatory behavior that support the notion that individual constitutional influences may strongly affect breed propensities toward intraspecific trait and predatory aggression, since other sled dogs raised under similar circumstances did not show the sort of extreme aggression exhibited by these dogs. After bilateral mechanical disruption and aspirative ablation of the prefrontal cortex, several of the dogs showed a pronounced reduction of fighting and killing behavior, without impairing their drive to pull a sled. In contrast, many of the family dogs presenting with domestic aggression problems showed improvement while in the laboratory, but little of this change transfered to the home, consistent with a complex etiology involving both genetic vulnerability and additive experiential influences.

NEUROBIOLOGY AND LOSS OF ADAPTABILITY

Neuopeptides, Monoamines, Impulsivity, and the Dissolution of the Bond

Aggression is of particular interest from a theoretical cynopraxic standpoint insofar as it represents the castastrophic dissolution of the social bond and thus mirrors in reverse significant factors influencing the bonding process. Social interaction perceived as ambiguous, uncertain, or uncontrollable (i.e. portending a potential loss or risk) may acutely activate NE and DA pathways in the process of enhancing vigilance (NE) and readiness (DA) to cope with the challenge or threat. The arousal mediating impulsive CDA probably originates at a preattentive level that reaches a catastrophic point of no return while the dog is preoccupied with conflict monitoring, suggesting that the diversion of attentional resources away from executive prefrontal functions to cope with social conflict may play a critical role in the mediation of impulsive aggression (see *Cortical and Subcortical Comparator Functions and Adaptation*). The risk of catastrophic impulsivity and aggression is particularly high in the case of ambiguous (uncertain) social signals or social demands forcing the dog to make conflict-laden choices between unacceptable alternatives. According to this hypothesis, chronic social ambivalence and entrapment diverts attentional resources away from executive functions (selective attention and impulse control) to conflict monitoring, a process that disrupts the dog's ability to competently regulate emotion, integrate an adaptive coping style, and to competently inhibit or disinhibit aggressive impulses.

Although a causal linkage between frontal serotonergic activity and aggression in dogs has not been definitively established, speculation implicating 5-HT in the etiology of aggression has long circulated in the applied and veterinary literature. However, most of this speculation has focused on the aggression-facilitating effects of 5-HT deficiencies. The present hypothesis suggests that both deficiencies and excesses of prefrontal 5-HT and DA may promote impulsivity (Dalley et al., 2002) and aggressive behavior (see De Boer et al., 2003). Depending on the specific receptor subtype, 5-HT appears to exert variable inhibitory and disinhibitory neuromodulatory effects over motivated behavior. On the one hand, psychological stressors may alter 5-HT function by various mechanisms. The adverse effects of altered 5-HT activity may be further amplified or attenuated by changes to the 5-HT transporter. For example, the principle antianxiety and antiaggression benefits of serotonergic medications is probably mediated by the inhibition of 5-HT transporters, thus enhancing the neurotransmitter's capacity to linger longer in the synaptic cleft and to modulate other neurotransmitters and neuropeptides conducive to relaxation, social attraction, and an adaptive coping style. In contrast, however, under the

influence of excessive 5-HT activity, some 5-HT receptors may mediate problematical inhibitory or disinhibitory influences over impulsive and reactive behavior via disruptive interaction with glutaminergic, dopaminergic, and GABAergic pathways. Depending on the type and chronicity of the stressors involved, stress-mediated deficiencies or excesses of 5-HT and DA may perturb selective attention, impulse control, and mood. According to this hypothesis, chronic stress results in disturbances affecting 5-HT modulatory function, while disrupting the integrative functions of DA, thereby impairing the dog's ability to organize control modules in a proactive and competent fashion. Effective cognitive processing and emotional regulation requires a precise balance of inhibitory, disinhibitory, and excitatory neuromodulation, that is, autonomic attunement and allostasis.

Oxytocin- and AVP-containing neurons express a variety of 5-HT receptor subtypes that promote a diversifying function on arousal and behavior (see *Oxytocin, Arginine Vasopressin, and Autonomic Attunement* in Chapter 8) via the release of oxytocin and AVP in response to stress. Both oxytocin and AVP neurons express $5HT_{2A/C}$ receptors, but only oxytocin neurons express $5\text{-}HT_{1A/B}$ receptors (Jorgensen et al., 2002). $5\text{-}HT_{1A}$ receptors may exert a major modulatory effect over the antianxiety and antiaggression effects mediated by oxytocin. $5\text{-}HT_2$, $5\text{-}HT_4$, and $5HT_7$ receptors appear to play prominent roles in AVP-mediated behavioral and physiological effects (Jorgensen et al., 2003a). Also, circulating cortisol entering the brain appears to selectively inhibit AVP and CRF release but spares oxytocin, leaving it unchanged (Papanek and Raff, 1994), suggesting that central oxytocin may perform a post-stress calming effect, consistent with an amnestic reconciliation function. Petting the stressed dog may facilitate this calming forgetfulness and facilitate social attraction by augmenting the release of central oxytocin. The oxytocin stimulating effects of petting and praise (vocal petting) appear to mediate the cumulative bond-enhancing and calming effects of basic training (see *Neuropeptides and Social Behavior* in Chapter 4 and *Oxytocin-opioidergic Hypothesis* in Chapter 6).

During episodes of acute stress AVP appears to augment the CRF-mediated release of adrenocorticotropic hormone (ACTH) (Klingbeil et al., 1988). Keck and colleagues (2002) found that an AVP receptor antagonist blocks the stimulatory effect of CRF on ACTH release in high-anxiety rats, supporting the hypothesis that AVP plays a mediational role in the expression of individual differences in response to acute psychological stressors. Although acute stress facilitates the production of both AVP and CRF, chronic stress exerts a differential upregulating effect on AVP while downregulating CRF activity (Ma and Lightman, 1998). As a result of exposure to chronic restraint stress, both CRF and glucocorticoid activity are reduced over time, whereas AVP gene expression is increased. The $5HT_{2A}$ receptor is known to control the release of AVP at the paraventricular nucleus (Ramage, 2001; Jorgensen et al., 2003b) and to modulate NE release by the locus coeruleus (Millan, 2003), while NE regulates the release of CRF (Itoi et al., 1999), which in turn modulates the release of 5-HT via the dorsal raphe nucleus (Thomas, et al., 2003) (see *Septal Distress, Relief, and Panic*). The notion that glucocorticoid activity decreases over time while AVP levels increase draws into question the value of cortisol levels as an objective index for assessing the welfare implications of chronic stressors, suggesting that AVP levels and AVP-related indicators such as antidiuresis, thermogenesis (elevated body temperature), cardiovascular changes as reflected in heart rate, heart rate variability (HRV), and blood pressure, and other compensatory behavioral and physiological adjustments (e.g., persistent hyperpnea), might represent more useful endophenotypic markers of allsostatic load resulting from chronic stress than isolated cortisol levels (see *Restraint, Unavoidable Aversive Stimulation, and Stress*). The foregoing findings suggest that exposure to chronic psychological stress (social ambivalence and entrapment) may promote either allostatic hyperdrive (high cortisol) or hypodrive (low cortisol) depending on the neural systems activated

and the nature of the stress. Whereas acute stressors activate reactive adjustments in association with allostatic hyperdrive and *hypercortisolism*, exposure to chronic stress and allostatic hypodrive in association with increased NE and AVP activity may switch on a PSM conducive to impulsivity.

Social exchanges posing difficult to discriminate options or ambiguity are a source of significant distress for dogs operating under the influence of entrapment and social ambivalence. The diversion of attention to monitor conflict may drain the executive resources needed to process and select behavioral options. With the reduction of executive capacities to maintain selective attention, the nodal regulation of sympathetic arousal may be disrupted, threatened with dissolution, and loss of impulse control. The resulting state of reactive readiness and vigilance may rapidly saturate available inhibitory networks and flood the dog with emotional pain and anger. Thus, impulsive CDA appears to involve the breakdown of the autonomic attunement and mutual awareness that emerges in response to social exchanges that mediate the friendly familiarity, belongingness, and the caring protectiveness of secure attachments. If the owner at such times would merely withdraw from the dog, the sequence of events might be averted, allowing dysregulated arousal to subside and the threat to pass. However, if the dog is further aroused by encroachment and nervous ambiguity or worse yet physical punishment it appears to enter a momentary state of utter incompetence and confusion or lapse of awareness as a catastrophic flash point of no return is reached. Hoaken and colleagues (2003), referring to disturbances of impulse control in human aggressors, nicely state the situation with respect to impulsive CDA, as well:

> Aggression is a primal social response option, a simple response option to an exceedingly rich and complex mélange of contextual cues. It may be that individuals with poor ECF (executive cognitive functioning), demonstrating poor social information processing skills and an inability to cope with overwhelming response options, fail to access more socially appropriate options and make default aggressive responses to provocative situations. (28)

Stress, 5-HT_{2A} Receptor Upregulation, and Aggression

Recent developments in neurobiological research are making significant progress with respect to getting a handle on the neural disturbances contributing to the development of impulsive CDA. For example, a neuroimaging study performed by Peremans and colleagues (2003ab) suggests a possible link between impulsive aggression and an imbalance of central serotonin activity. The researchers found that dogs with a history of serious aggression problems show evidence of increased 5-HT_{2A} receptor binding potential in frontal cortex. No significant differences were found in the receptor binding characteristics of aggressive and nonaggressive dog with respect to 5-HT_{2A} receptor expression in subcortical areas. Nor were there significant differences between aggressive and non-aggressive dogs in terms of regional cerebral blood flow. The aggressive dogs studied were referred for imaging by behavioral consultants and all of the dogs had been diagnosed with "dominance aggression." Precisely why aggressive dogs show increased cortical 5-HT_{2A} receptor binding potential is unknown, but at first glance, given the common assumption that "dominance aggression" is due to a lack of synaptic 5-HT, one might be tempted to interpret the increased binding potential as an adaptive upregulation of receptor activity in response to decreased 5-HT (Walsh and Dinan, 2001). The upregulation hypothesis is problematical since the 5-HT_{2A} receptor does not appear to upregulate in response to reduced synaptic 5-HT (Peremans et al., 2003b). Although chronic exposure to decreased 5-HT release might result in alterations affecting 5-HT_{2A} receptor sensitivity and numerous other changes influencing 5-HT function, decreased 5-HT levels alone might not account for the receptor binding changes found in aggressive dogs. Another possible explanation for the increased binding index exhibited by such dogs is prior exposure to antidepressant medications commonly used to treat canine aggression problems. Chronic fluoxetine treatment in rats has been shown to significantly increase the density of 5-HT uptake sites and to upregulate the expression of 5-HT_2 receptors in the frontalparietal cor-

tex by 31-38% (Hrdina and Vu, 1993). However, none of the dogs enrolled in the present study had ever received psychotropic drugs, modified diets, or behavioral therapy prior to the imaging study (Peremans, personal communication, 2003), thus excluding a drug effect as a possible explanation. The lack of differences between aggressive and nonaggressive dog pertaining to cerebral blood flow is a bit surprising and might represent an artifactual peculiarity of the study design, which required that the dogs be anesthetized for brain imaging.

Early developmental stress may exert influential effects on the organization of reactive thresholds. Prenatal stress has been shown to promote widespread changes affecting the organization of most major neurotransmitter systems so far studied (see *Ontogeny, Coping, and Social Behavior*). In addition to the impact of elevated maternal glucocorticoids reaching the fetal brain, perinatal gonadal hormones may alter the expression of serotonergic pathways in the young dog that may affect the adult dog's vulnerability to psychological stress. Early social stressors have been implicated in numerous neurophysiological changes relevant to attachment problems and aggression, including the upregulation of the 5-HT_{2A} receptor. For example, rats given corticosterone or ATCH for 10 days show a significant increase of 5-HT_{2A} receptor binding potential in the frontal cortex (Takao et al., 1995; Takao et al., 1997; Kuroda et al., 1992). Also, cortisol has been shown to increase the expression of 5-HT transporter sites in vitro (Tafet et al., 2001), raising the possibility that increased glucocorticoid levels resulting from chronic stress might increase the re-uptake efficiency of serotonergic terminals, causing 5-HT to be rapidly cleared from the synaptic cleft. Such an enhancement of 5-HT transport could result in the premature termination of 5-HT-mediated neural transmission. Under a highly motivated state, rapid clearance of 5-HT could result in muddled judgment, behavioral dysregulation, and the catastrophic sequencing and loss of control associated with impulsive aggression.

In addition to stress-related endocrine changes, sex steroids also appear to exert an upregulating effect on 5-HT_{2A} receptors in frontal and cingulate cortical areas of rats (Sumner and Fink, 1998). Male rats show a greater concentration of 5-HT_{2A}-receptor activity in the ventromedial hypothalamus, a gender dimorphism that is eliminated by castration (Zhang et al., 1999). The ventromedial hypothalamus is associated with the expression of affective aggression [see *Neurobiology of Aggression (Hypothalamus)* in Volume 1, Chapter 3]. Isolation rearing can also enhance 5-HT_{2A} receptor binding and increase aggressive behavior (Sakaue et al., 2002), conversely, enhanced 5-HT_{1A} receptor activity appears to exert an antiaggression influence. Similarly, among cats the 5-HT_{1A} receptor appears to mediate an inhibitory effect over affective aggression, whereas the 5-HT_2 receptor may facilitate it (Gregg and Siegel, 2001). 5-HT_{1A} agonists exert potent inhibitory effects on 5-HT_{2A}-mediated behavior as well as downregulating the 5-HT_{2A} receptor (Eison and Mullins, 1996). 5-HT_{1B} agonists have also been shown to exert a potent inhibitory effect on aggression between rats facilitated by frustration and social instigation (de Almeida and Miczek, 2002). Interestingly, a prominent effect of 5-HT_1 receptors is to exert an inhibitory autoreceptor effect over the release 5-HT, with 5-HT_1 agonists reducing synaptic 5-HT availability.

Panic, Separation Distress, and Aggression

Increased dopamine (DA) activity stimulated by apomorphine has been shown to upregulate the 5-HT_{2A} receptor as well as to facilitate the expression of impulsive behavior, including aggression in predisposed animals (Matto et al., 1999), however, increased 5-HT_{2A} activity does not appear to alter the latency or intensity of apomorphine-mediated aggressive behavior, at least among rats (Skrebuhhova-Malmros et al., 2000). Aggression mediated by dopaminergic pathways may either be facilitated or inhibited by 5-HT_2 receptor activity depending on the cortical or subcortical site and the receptor subtype involved. For example, the 5-HT_{2A} receptor appears to mediate a phasic disinhibitory influence (i.e.,

lifts tonic inhibition) over cortical DA release in response to anticipated social stressors, while 5-HT_{2C} receptors appear to exert a tonic inhibitory effect (Gobert and Millan, 1999). At the level of the ventral tegmental area (VTA), 5-HT_{2C} appears to promote phasic and tonic inhibitory influences over the release of DA (Di Matteo et al., 2002), whereas the 5-HT_{2A} receptor mediates a phasic disinhibitory influence over DA release. Prefrontal regulatory influences over mesolimbic reward circuits is also mediated by the modulatory effects of 5-HT on excitatory glutaminergic pathways projecting to the VTA and the nucleus accumbens (Charney, 2004). In addition to receiving glutaminergic input from the amygdala, the thalamus also communicates with the mPFC via a glutaminergic circuit (Martin-Ruiz et al., 2001)—a circuit that might produce significant disruption of executive function and perceptual disturbance in cases where 1A- and 2A-receptor activity is in a state of flux or imbalance. Elevated DA activity, increased 5-HT_{2A} receptor binding potential, and disturbances affecting 5-HT or DA clearance within the PFC may combine to produce devastating cognitive disturbances. Hallucinogens (e.g., LSD) exhibit a high affinity for the 5-HT_{2A}-receptor subtype, suggesting the possibility that some impulsive attacks may be associated with perceptual confusion or hallucination.

Prefrontal 5-HT and DA systems undergo alteration as the result of aggressive interaction. Van Erp and Miczek (2000), for example, have shown that episodic fighting between rats produces a potent effect on prefrontal DA and 5-HT balance, resulting in a sustained 120% increase of DA and an 80% decrease of 5-HT turnover in the mPFC. In a parallel study performed in the same laboratory, found that repeated aggressive encounters between rats resulted in conditioned changes in heart rate and the release of DA and 5-HT in anticipation of a fight (Ferrari et al., 2003). In this study, aggressive rats were brought together to fight on 10 consecutive days at precisely the same time. On day 11 the scheduled fight was cancelled and various real-time measurements were taken to assess 5-HT and DA activity. During the hour immediately before the usual fight time, the rats showed a conditioned increase of heart rate and a potent efflux of accumbal DA. The 5-HT levels of experienced rats stayed relatively constant throughout, until approximately several minutes before the normally scheduled fight, whereupon 5-HT levels dipped and decreased by 30-35% over the next hour or so before slowly returning to baseline levels. During the first fight encounter, in contrast, 5-HT levels showed a slight dip during the fight period itself and remained relatively steady for 30 minutes, during which time DA levels increased with the onset of the fight and continued to increase over the course of the same 30-minute period. The subsequent increase of DA appeared to shadow a decrease of 5-HT levels, suggesting that 5-HT may exert an inhibitory effect on DA activity, perhaps via the action of the 5-HT_{1A} autoreceptor. Taken together these findings suggest that DA establishes a motivational readiness to fight, whereas 5-HT may either inhibit or disinhibit aggressive behavior, thereby forbidding or permitting aggression but without directly affecting the motivational state. Surprisingly, in contrast to the conditioned changes in DA and 5-HT levels, the rats that fought showed only a slight increase of anticipation-related heart rate change in comparison to control mice that had not fought.

The feed-forward or proactive nature of preparatory aggressive arousal is also true for the way dogs cope with social stressors, explaining why the same aversive event might activate the HPA system or not depending on the degree of control or *power* (competence and confidence) that the dog perceives it has over the event. The foregoing findings support the idea that aggressive exchanges are under the regulatory influence of feed-forward conditioning effects. The evident adjustment and coordination of DA and 5-HT activity in anticipation of events, including the preparation of physiological states required to enable the animal to cope effectively with impending motivational demands strongly supports the notion that aggressive behavior can be regulated by control expectancies and emotional establishing oper-

ations integrated in the process of establishing an adaptive coping style. Psychological stressors perceived as uncontrollable challenges or threats exert a disorganizing effect (reactive coping style), whereas the same aversive motivation stimuli, when perceived as predictable and controllable, generate an organizing effect on behavior (adaptive coping style) precisely because adaptation is organizational and designed to learn and cope proactively with motivational challenges and threats rather than to merely react to them. These observations support the hypothesis that reward and punishment in association with positive and negative prediction error is critically dependent on the nucleus accumbens and its interconnectivity with the orbitofrontal cortex, amygdala, and VTA, neural processing networks that regulate the expression of motivated behavior in accord with proactive prediction-control expectancies and calibrated establishing operations.

Septal Distress, Relief, and Panic

The septum pellucidum is a limbic structure believed to perform a number of important functions in learning and the regulation of endocrine activity and emotion by virtue of its close relationship with the hippocampus and interconnectivity with the amygdala, the hypothalamus, the cingulate cortex, and the PAG. Reciprocal communication between the septum and the hippocampus occur via cholinergic tracts, with septal signals providing a pacemaker effect on hippocampal theta rhythms as well as serving to switch the hippocampus from an information processing mode to information collecting mode (Ikonen, 2001). The septum plays an important role in the process of forming expectancies about the timing and contingency of unconditioned stimuli (Garcia and Jaffard, 1996). Under the influence of aversive arousal septal stimulation appears to produce reward (relief), whereas under nonthreatening circumstances septal stimulation is hedonically neutral (Grauer and Thomas, 1982), suggesting that the septal-hippocampal connectivity may mediate passive avoidance, anxiety, and relief, whereas the central amygdala and the BNST are involved in the elaboration of fear and active avoidance. Medial septal lesions appear to significantly impair an animal's ability to respond adaptively to signals of punishment and nonreward (Gray, 1971). Impaired animals show deficits with respect to the inhibition of an activity once it has started, despite the presence of clear signals of punishment and nonreward. Unable to respond to stop signals, septal-impaired animals may nevertheless remain acutely aware that they are threatened by an impending loss or risk resulting from their failure to stop.

In response to emotional alarm or uncertainty, the central amygdala may activate anxiety-mediating excitatory pathways that reach the lateral septum via the paraventricular nucleus (PVN) and the BNST (Nail-Boucherie et al., 1998). Also, efferent AVP fibers project from the medial amygdala to the ventral hippocampus as well as the lateral septum directly and via the BNST (Caffe et al., 1987), suggesting that CRF and AVP (see DeVries et al. 1983) may synergistically interact in the lateral septum to mediate anxiety- and distress-related behavior. Interestingly, Thomas and colleagues (2003) have shown that CRF exerts a regulatory effect at the level of dorsal raphe nucleus over the release of 5-HT in the lateral septum, with low levels of CRF reducing septal 5-HT release and high levels of CRF increasing septal 5-HT release. This pattern of connectivity may promote a durable state of aversive arousal and punishment-resistant vigilance in response to a variety of acute psychological stressors requiring caution and persistence but not escalating into a state of reactive fear or anger. Significantly, paroxetine exerts an inhibitory effect over the release of 5-HT via the 5-HT_{1B} autoreceptor, an effect that takes place most prominently in the ventral hippocampus (Gardier et al., 2003). 5-HT also appears to modulate cholinergic transmission via postsynaptic 5-HT_{1B} receptors expressed on the terminals of cholinergic neurons within the hippocampus. Fish and colleagues (2000) have shown that 5-HT_{1B} agonists mediate a suppressive effect over mouse distress vocalization to maternal separation (Fish et al., 2000), suggesting a possible mechanism for the bene-

ficial effects of paroxetine for the control of separation distress and panic. Consistent with this hypothesis, nicotine, a cholinergic agonist, has also been shown to decrease separation distress vocalizations in chicks, whereas the antimuscarinic scopolamine increases distress vocalizations (Sahley et al., 1983). Further, the electrical stimulation of the ventral septum produces a high level of separation-distress vocalizations, as does stimulating the BNST (Panksepp, 1998). Recently, Degroot and colleagues (2004) have reported that the septal-hippocampal system plays a prominent role in the modulation of different anxiety states via glutaminergic, GABAergic, and cholinergic pathways. Finally, GABAergic plasticity at the level of the septum determines how animals cope with inescapable stressors, with the stress-mediated downregulation of septal $GABA_B$ receptors appearing to exert a protective influence against learned helplessness (Kram et al., 2000). In addition to the panic occurring in association with separation distress, the lateral septum and BNST may also play a role in mediating the panic associated with certain forms of aggression expressed in association with a reactive coping style (see Koolhaas et al., 1998).

The panic and persistence associated with separation distress is consistent with what one would expect to occur in association with faulty septal-hippocampal processing, whereby the dog appears to become "obsessively" fixated on an expectation of impending relief, despite foreknowing (signals of nonreward) that the owner will not likely come home any time soon, consistent with impairments affecting passive avoidance learning. The precise etiology of such problems is unknown, however, it is reasonable to suggest that social ambivalence and entrapment occurring in association with insecure or nervous attachments may promote complex disturbances disrupting glutaminergic, GABAergic, opioidergic, or cholinergic transmission and that these dynamics might produce a detrimental imbalance at the level of the septum and other limbic areas conducive to separation distress. The involvement of these systems in the mediation of separation distress may help to explain why people often increase their consumption alchohol, sugar, sweet and fatty dairy products (e.g., ice cream), and tobacco at times involving social loss and separation. The consumption of sugar, for example, may produce a self-medicating effect via a glucose-mediated reduction of opioid restraint over cholingergic activity, whereas nicotine consumption may alter activity in cholinergic-dopaminergic pathways. Ragozzino and colleagues (1992) found that passive avoidance was impaired when morphine was injected into the medial septum, whereas the administration of glucose reversed the deficit. Under the influence of an insecure attachment heightened oxytocin activity may mediate a sensitization to opioid and DA activity, making the dog vulnerable to opiate-like addiction and withdrawal symptoms when the insecure social attachment object maintaining DA, opioid, and oxytocin levels is withdrawn. Interestingly, clomipramine, a drug commonly used to treat separation-related problems, reduces central opioid levels, down regulates opioid-binding sites, and attenuates morphine-induced analgesia. In addition, among humans, clomipramine has been shown to increase oxytocin and to decrease CRF levels in the cerebral spinal fluid (CSF) (McDougle et al., 1999), perhaps contributing to the stabilizing effect that the medication appears to exert over canine separation distress.

The finding that glucose interacts with opioids in a function-restoring fashion, suggests that at least in some cases of separation distress, a sugar pill may be more than just a placebo. Also, given the apparent attenuating effects of nicotine on separation distress, it would be interesting to learn whether there is any discernable relationship between cigarette smoking in households with dogs and the risk of separation-related problems. Whether feeding the dog sweet-flavored treats or giving it toys that have been coated with a sweet solution would have any benefit on separation-related problems is unknown but such research may be interesting to pursue, since the dog definitely has a sweet tooth (Ferrell, 1984). Among human infants undergoing painful medical procedures, sucrose and non-sucrose sweeteners have been shown to dimin-

ish signs of pain for up to 5 minutes, with peak effects observed at 2 minutes after ingestion (Blass and Shah, 1995). These findings suggest the obvious possibility that similar benefits might be obtained in the case of puppies and dogs receiving vaccination shots or undergoing painful grooming procedures (e.g. cleaning ears). In addition to analgesic effects, among rat pups that have been separated from their mother, ingestion of sucrose also produces a calming effect in the distressed infant (Blass et al., 1987). Milk also appears to produce similar effects among infant rats (Blass and Fitzgerald, 1988), apparently not as result of lactose (Blass and Shide, 1994), but perhaps due to the casomorphine contained in milk casein or as the result of milk fat. The calming effect of sucrose on separation distress is robust, reducing distress vocalizations by 50% (Blass and Shide, 1994). Interestingly, with respect to the cholinergic-opioid hypothesis outlined above, the analgesic effect of sweet substances appears to be mediated by nicotinic cholinergic receptors (Irusta et al., 2001). Casual observations by the author indicate that small amounts of whipped cream or soft cheese delivered from a pressurized can do seem to mediate a transient comforting effect. The use of food items may provide benefits in the case of puppies that are overly resentful or reactive to routine veterinary or grooming procedures. In any case, given the reports from human and animal studies of an analgesic effect, some investigation is warranted to explore whether food items such as whipped cream or soft cheese might be useful for reducing the discomfort and fear associated with veterinary examinations and treatments. The first visit is the most critical since those impressions are extremely durable. Using a combination of food, odors, petting/massage, and toys might help to reduce the risk of the dog forming lasting aversive associations linked to veterinary visits, while at the same time promoting positive expectations.

Periaqueductal Gray and Autoprotective Adjustments to Social Stressors

Social disengagement, confrontation, and aversive communication systems appear to converge subcortically at the level of the PAG (periaqueductal gray) (Keay and Bandler, 2001). The PAG projects to the nucleus ambiguous (Farkas et al., 1997) where it may increase heart rate and blood pressure and participate in the expression of threat displays (e.g. direct stare, snarling, ears forward, and growling) (lateral PAG) or decrease heart rate and blood pressure and contribute to the expression of defeat and appeasement displays (e.g., averted eye contact, head down, ears pinned back, and yelping) (ventrolateral PAG). Active and passive coping reactions in response to threats are under the regulatory influence of both cortical and limbic pathways (e.g., amygdala, hippocampus, and hypothalamus) (see *Stress-related Potentiation of the Flight-Fight System* in Chapter 6). These reactions include emotional vocalizations expressing distress, discomfort, and alarm/threats, social communication that appears to be mediated by the PAG and vocal-motor nuclei located in the brainstem. The strong connectivity between the prefrontal cortex and the PAG emphasizes the role of psychological stressors (e.g., violations of prediction-control expectancies) on the development of fear and aggression problems. PAG flight-or-fight adjustments appear to be under the modulatory control of reciprocal inhibition, that is, when PAG flight networks are activated PAG fight programs may be actively restrained while a converse effect appears to occur when the fight network is activated (Jansen et al., 1998). The rostral aspects of the dorsolateral (dlPAG) and lateral (lPAG) columns of the PAG mediate confrontational threat and attack (anger) (fight system), while the caudal aspect of the dlPAG and lPAG mediate the mobilization of defensive escape (fear) (flight system). The rostral portion of the lPAG receives ascending somatosensory input originating from the face and forelimbs, whereas the caudal portion of the lPAG receives afferent input from the lower portion of the body. This organization of somatosensory organization suggests that frontal threats are more likely to evoke anger and offensive aggression than threats coming from behind, which are more likely to evoke fear and defensive adjustments. The ventrolat-

eral PAG (vlPAG) mediates opioid-mediated analgesia, bradycardia and hypotension, and tonic immobilization, suggesting that the vlPAG plays a role in facilitating the aggression-suppressing effects of repeated social defeat (Depaulis et al., 1994).

When the dog is challenged or threatened in a serious way a pathway linking the medial amygdala, the bed nucleus of the stria terminalis (BNST) (an area that may promote intensified vigilance at such times), and the medial hypothalamus may be activated to mobilize an avalanche of neurophysiological activity at the level of the PAG that might promote catastrophic autoprotective adjustments. Both the rostral and caudal aspects of the lPAG and the dlPAG produce tachycardia and hypertension but do so in association with different patterns of vasodilation and vasoconstriction. Defensive arousal associated with the caudal lPAG results in a diversion of blood from the head and viscera to the skeletal muscle. In contrast, offensive arousal associated with the rostral dlPAG result in an increased heart rate and blood pressure associated with a diversion of blood from the skeletal muscles and viscera to the head via increased extracranial blood flow. The vasodilation and increased blood flow associated with dlPAG offensive arousal may explain the reddish glow that dogs show immediately before launching into an attack. Unlike the lPAG, the dlPAG column receives no significant spinal, trigeminal, or medullary inputs, but is strongly enervated by descending inputs from the right mPFC. These mPFC efferent pathways also target the anterior and ventromedial hypothalamus, a pattern of connectivity that suggests that the mPFC in coordination with the hypothalamus serves to modulate the expression of aggression and escape behavior (Keay and Bandler, 2001). The lPAG receives strong cortical enervation from the cingulate area (An et al., 1998), perhaps mediating aversive state arousal and behavioral activation associated with the detection of social conflict and loss. Kyuhou and Gemba (1998) found that the area of the guinea pig PAG that evokes separation-distress vocalizations, receives "massive input" from the ACC, lending support to a possible linkage between separation distress/panic and the PAG.

PART 2: BONDING THEORY

Ontogeny, Coping, and Social Behavior

The disorganizing influence of runaway allostatic load and the integration of maladaptive behavioral phenotypes may be initiated or prefigured early in a dog's ontogeny. Dogs exposed to adverse prenatal and postnatal stress, perinatal trauma, or maternal maltreatment may show a more dramatic and exaggerated allostatic response and tendency to integrate adaptation-impairing load in response to stressors than dogs exposed to more favorable ontogenetic programming early in life. The type, amount, and timing of early stress may profoundly affect the expression and functionality of PSMs and the ability of a dog to adjust in a functionally coordinated way. Developmental programming and insults that cause modal disturbances affecting sensorimotor processing (preattentive and preemptive arousal) and various motivational and motor systems integrating drive and behavioral output may impair a dog's ability to achieve coherent and stable adjustments.

In addition to psychological stressors, damage associated with infectious disease and environmental toxins have been implicated in etiology of adult and childhood behavioral disorders. Mothers exposed to viral infections early in the gestation period may transmit pathological antibodies or cytokines across the placenta that produce lasting harmful effects. Rat mothers, for example, infected with influenza virus during day 9 of gestation showed alterations in exploratory activity, including increased aversion toward novelty together with deficits affecting prepulse inhibition in response to auditory startle (Shi et al., 2003). Brown and colleagues (2004) have reported that babies born to mothers exposed to influenza during the first trimester showed a sevenfold increase in risk for developing schizophrenia in adulthood. Since the influenza virus only rarely crosses the placenta, the researchers implicate maternal immunoglobulin G antibodies activating fetal

brain antigens or a virus-induced excess of maternal cytokines. Infant exposure to environmental toxins has been implicated in the expression of a wide spectrum of behavioral disorders, including attention-deficit hyperactivity disorder, retardation, and autism (Zoeller et al., 2002; Colburn, 2004). The effects of thyroid are pervasive and time dependent, affecting the organization of neural tissue and connectivity via myelination and synaptogenesis. Thyroid plays a significant role in the organization of the glucocorticoid, cholinergic, and serotonergic systems and the structural development of the cortex, basal forebrain, cerebellum, hypothalamus, and hippocampus (Meaney et al., 2000; Thompson and Potter, 2000; Smith et al., 2002; Zoeller et al., 2002). The prenatal role of thyroid in the development of neuronal systems mediating the organization of social coping styles emphasizes the importance of fetal thyroid balance. Exposure to a variety of common medications and cytokine-producing vaccinations during the first trimester of gestation may exert far-reaching effects on a progeny's behavioral adaptability in adulthood (see *Antistress Neurobiology, Maternal Care, and Coping Style* in Chapter 8 and *Immune Stress and Cytokines* in Chapter 6).

Although PSMs and the various interconnected modal networks and motor programs subserving their development and expression may remain relatively quiescent and unintrusive under the influence of minimal change and stress, dormant dysfunctional modes may be activated later in life under the influence of psychological stressors or in association with epigenetic shifts heralding major developmental transitions (e.g., puberty and adulthood). These late epigenetic elaborations and patches may be particularly vulnerable to disorganization and instability. Under the influence of aberrant polymorphisms or stressors, problematic PSMs may integrate at an age-inappropriate time and thereafter exert adverse epigenetic changes to modal drive networks and emotional command systems. For example, paedomorphic behavioral phenotypes may be the result of such developmental delays and shifts in organization serving to prolong youthful sociability and playfulness, with many dogs appearing to operate under a predominant play drive. Late developmental epigenetic elaborations or patches that add on to or activate modal networks and motor programs organized early in life but left in a dormant state (e.g., the gender dimorphic effects of perinatal sex hormones) are prone to mobilize instability and allostatic load when mediating disruptive social dynamics associated with social ambivalence and entrapment. Accordingly, dormant dysfunctional PSMs activated while adult sociosexual phenotypes are being elaborated may be particularly sensitive to conflictive social dynamics, dispersive tensions, and show an increased vulnerability for the expression of reactive and impulsive behavior.

The dysfunctional mode and subservient modal networks may become progressively autonomous and disruptive while degrading or abolishing executive control and fostering a reactive coping style associated with accumulating allostatic load, ambivalence, and entrapment. Under the influence of social and environmental stressors perceived as inescapable (entrapment), a dog may attempt to adjust by retracting the SES while disengaging executive attentional resources, giving rise to dispersive tensions (e.g., resentment, irritability, and intolerance) and autoprotective dynamics, on the one hand, and mediating persistent anxiety, autonomic deregulation, and impairment of the dog's ability to cancel/inhibit or activate/disinhibit autonomic and emotional processing appropriately in coordination with purposive drive and functionally appropriate behavior (see *Breed and Individual Difference and Reactive/Impulsive Behavior*).

Prenatal Stress: Born to Flee or to Bite?

The enduring developmental effects of prenatal stress have been traced to various changes in all major neurotransmitter systems (Weinstock, 1997). In addition to altering NE and serotonin (5-HT) activity, prenatal stress reduces DA turnover in the nucleus accumbens while increasing DA turnover in the PFC. Chronically elevated DA activity in the PFC may disrupt executive attention and impulse-control functions (see *Startle and Fear Circuits* in Chapter 3), whereas a reduc-

tion in DA turnover in the mesolimbic system may diminish an animal's ability to produce reward and mobilize reward-dependent active modal strategies (e.g., exploratory behavior and social engagement). In fact, animals exposed to prenatal stress have been shown to exhibit a diminished responsiveness to reward (Matthews et al., 1996; Matthews and Robbins, 2003). The intrinsic reward that mediates play appears to depend on a balance of DA and opioid activity, whereas acetylcholine and NE appear to be involved in the cognitive, exploratory, attentional, and arousal aspects of play behavior (Vanderschuren et al., 1997; Panksepp, 1998).

Developmental perturbations of the DA reward system would likely disrupt a young dog's ability to refine control modules, thereby adversely influencing its ability to integrate adaptive behavior. Such prenatal disturbances affecting reward processing suggest an explanation for the *reward resistance* exhibited by some dogs to behavior-therapy procedures dependent on the conditioning of reward signals. The tendency of unstable introverts to show a heightened sensitivity to signals of punishment and a reduced responsiveness to signals of reward is consistent with a prenatal origin of such temperament differences as well as the anxious/irritable dysthymia exhibited by such dogs. In addition to an increased sensitivity to stimuli producing anxiety and a blunted responsiveness to reward, prenatal exposure to maternal anxiety and anger may program neurobiological changes that might confer an increased risk for developing behavior problems associated with anger and impulsivity in adulthood. For example, babies born to high-anxiety, angry, and depressed mothers show parallel biochemistry profiles (low DA and 5-HT levels), decreased vagal tone, and right hemisphere electroencephalographic asymmetry (Field et al., 2003), perhaps predisposing them to integrate similar mood and behavioral propensities.

Postnatal Handling: Protective and Destructive Influences

Postnatal stimulation may accentuate, diminish, or reverse the adverse effects of prenatal stress. Whereas long periods of separation from the mother can result in HPA-axis disturbances in adult rats, briefer periods of separation tend to produce a moderating effect on emotional reactivity and HPA-axis activity. Adverse maternal separation stress produces a downregulation of glucocorticoid-binding sites in the hippocampus, as well as increases hypothalamic CRF mRNA expression. This combination of neural changes may result in an adult animal that is stress prone, showing a greater vulnerability to the adverse effects of chronic environmental and psychological stressors via impaired hippocampal negative-feedback control over CRF release and increased CRF activity. Although the stress-mediated facilitation of CRF gene expression exerts highly durable and perhaps irreversible changes on the CRF system, the brain shows remarkable capabilities to make compensatory adjustments. For example, among rats exposed to harmful maternal separation, social and environmental enrichment procedures ameliorate the adverse effects of early stress on HPA-axis activity and fearful responses to psychological stressors (Francis et al., 2002).

The critical factor affecting the long-term effects of early stress probably depends on the quality of maternal care received by an infant. Several studies have shown that it is not the *stress* produced by separating an infant from its mother or exposure to environmental insults, but rather the benefits are due to subsequent changes in the mother's caregiving behavior when the infant is returned to the nest (see *Antistress Neurobiology, Maternal Care, and Coping Style* in Chapter 8). Maternal caregiving behavior appears to be invigorated by the pup's absence from the nest and upon reunion the separated infant becomes the object of intensified exploratory interest, licking, and other maternal contact behaviors. Among rats, adoptive mothers are typically more attentive to adopted pups and tend to give them more grooming and licking than provided by natural mothers. Maccari and colleagues (1995) have shown that the increased care provided by adoptive mothers appears to reverse the adverse behavioral effects of prenatal stress on HPA-axis activity.

An infant's ability to cope with stress in adulthood appears to be mediated by an antistress system that is integrated by the central release of oxytocin in response to maternal licking and other caregiving activities. Repetitive stroking and other forms of stimulation similar in effect to maternal care and grooming have been shown to induce oxytocin release and to exert a protective influence or to reverse the effects of prenatal stress on developmental disorders in adult animals (Weinstock, 2002) (see *Handling and Gentling* in Chapter 4). The obvious implication of these various findings is that the amount and quality of maternal attention and care received by the infant exert a significant programming effect on adult coping styles (see *Ontogeny and Reactive Behavior* in Chapter 8).

Ontogeny, Olfactory Cortex, Attunement Nodes, Engrams, and Networks

During the first 2 weeks of life, a puppy is adapted to an off-line state dedicated primarily to nursing and sleeping (Fox and Stanton, 1967) adjusting as needed to internal and external stressors by means of an array of sensorimotor reflexes. Sensory inputs are reduced to a minimum with the eyes and ears remaining closed, but as these sensory channels open between weeks 2 and 3, respectively, a dog becomes increasingly active and interactive. By the time a dog reaches week 3, it already shows a strong preference for the smell of kin bedding (Mekosh-Rosenbaum et al., 1994) consistent with the existence of a motivated preference and attachment. At weeks 4 1/2 to 5 1/2 (Hepper, 1986), they orient, presumably using both auditory and visual channels (although auditory information may play a subordinate role), and ambulate into the proximity of familiar siblings and avoid other puppies of a similar age, breed, and sex. The olfactory memories and preferences integrated during this time appear to degrade with respect to the recognition of separated siblings but remains intact with respect to the reciprocal recognition shown mothers and offspring after 2 years of separation (Hepper, 1994). In addition to confirming these earlier studies, Gillis and colleagues (1999) have demonstrated that dogs not only recognize their mother but also recognize the scent of the breeder well into adulthood and probably for much of their lives (Appel et al., 1999).

With the onset of the socialization period at week 3, a rapid integration of corticohypothalamic networks and exchange-mediated autonomic attunement nodes emerges to regulate drive and emotion and to guide sympathovagal tone toward a state of balance conducive to alertness and social engagement (see *Socialization: Learning to Relate and Communicate* in Volume 1, Chapter 2). During these early weeks, social expectancies, autonomic attunement, and play facilitate increased social attraction and awareness. A puppy's ability to learn appears to reach a high level by weeks 7 and 8, abilities that may already start declining after week 16 (see *Learning and Trainability* in Volume 1, Chapter 2).

Weaning and Parent-Offspring Conflict

According to an influential theory of parental investment (PI) proposed by Trivers (1972), both parents invest in the care of offspring, but the PI of males is typically much less than that of females. In some species, such as dogs, the male PI consists only of donating sperm, whereas other mammalian males contribute more equitable investments to the care of the young. The amount of PI given by the mother and father appears to exert a profound influence on the reproductive relationship, the social organization of the group, and the quality of interaction among members of the group. Besides nurturance, a significant part of PI involves protection. Among wolves, mothers and fathers share a major investment in the care and protection of the young (Mech, 2000). They form lasting pair bonds, show evidence of a division of labor, and organize relatively stable family groups. The mother wolf suckles and cares for the young and protects the denning area, whereas the father appears to play a greater role in the defense of the home territory while provisioning the mother and young with food. In contrast, males in animal societies where they contribute minimal PI to their offspring may nevertheless contribute strongly to the gene

pool to the extent that they can compete successfully with other males seeking females to fertilize. In such animal groups, intermale competition may be more prominent, necessitating a variety of biological (e.g., endocrine control of agonistic thresholds) and social adaptations (e.g., dominance hierarchies) to moderate competitive tensions.

The weaning process exhibited by wolf mothers appears to be relatively peaceful, at least when adequate amounts of alternative food are available to feed the young. Packard and colleagues (1992) observed only one occasion prior to week 7 in which the mother terminated a nursing bout by muzzling a pup. From week 6 onward, however, they observed a trend toward more frequent mother-initiated terminations of nursing bouts and infant-directed agonism, culminating in weeks 8 and 9, when the mother terminates 80% of the nursing bouts by agonistic means. The use of muzzling to control nursing activity was usually associated with signs of discomfort on the mother's part (wincing). The wincing action itself acquired the ability to interrupt nursing. After the mother winced or muzzled them, the pups stopped nursing and did not persist.

Under domestic conditions, the mother and the breeder contribute the primary sources of PI in the care of puppies. In addition to giving the mother emotional support, the breeder assists the dam by feeding the puppies solid food or by confining the puppies or by helping the mother stay out of the offsprings' reach, perhaps by providing a ledge or other place for the mother to retreat. In the early stages of nursing, the mother appears to derive considerable gratification from the contact with her offspring (Korda, 1974), initiating nursing bouts and spending large amounts of time caring for them (Rheingold, 1963). Licking bouts are most frequent and lengthy during the first 2 weeks postpartum. As the mother's willingness to nurse declines toward week 4, there is an increase in offspring-initiated approaches and nursing bouts, which may rapidly exceed the mother's optimum PI and require the breeder's intervention to control. In addition to the food given to the puppies by the breeder, some canine mothers may regurgitate. Regurgitation serves to transition the puppy from the ingestion of the preferred mother's milk to the search for solid food (James, 1960; Malm, 1995). Martins (1949) observed that the appearance of regurgitation is closely associated with the decline in lactation and continues only a few days after weaning is complete, whereas Korda (1974) found that regurgitation routinely continued long after puppies were able to eat solid food—conflicting findings that suggest the existence of a high degree of individual variability affecting the habit. Domestic male dogs can be induced to regurgitate in response to et-epimeletic displays if they are confined in close proximity with puppies (Korda, 1974), but the tendency to provision food to offspring appears to be generally atrophied in male dogs. Feral male dogs may stay with the mother, sleep nearby, and even play with the puppies but do not provide the young with food (Macdonald and Carr, 1995). This lack of PI by male dogs is a peculiarity of domestication and in sharp contrast to the behavior of wild canids.

During weaning, the competent mother appears to calm the puppy with affectionate tactile stimulation, complementing the more energetic, playful, and competitive exchanges among littermates. Gently muzzled puppies may be transitioned to receive a sustained licking or nibbling bout, maternal activities that they appear to enjoy by rolling on their side or back, laying still, and often closing their eyes. Puppies may show signs of growing sibling agonism during this period of transition, but they rarely attempt to provoke such interaction with the mother. Often by means of the mildest assertions of maternal force, a puppy defers or walks away—a response that may be followed by the mother going to the puppy and intermittently mouthing or licking around the scruff of the neck. The mother appears to actively mediate a reconciliation process with the discouraged youngster. Contingent assertions of power, affectionate reconciliation, and periodic absences serve to reduce undesirable behavior while at the same time stimulating emotional establishing operations that prime conflict-resolving adjustments and compromise. The assertion of

maternal power mediates various passive modal activities (e.g., hesitating, waiting, and submissive ritualizing) that are valuable for promoting impulse control and cooperative behavior.

The conflictive dynamics of exchange between the mother and puppy appear to promote an emergent coping style consistent with many of Trivers' predictions regarding parent-offspring conflict (Trivers, 1974) (see *Parent-Offspring Conflict and Interactive Conflict* in Chapter 8). The puppy's efforts to get care in excess of the mother's parental investment, while avoiding punishment (e.g., loss of care and risk of physical restraint), provides a framework of positive and negative incentives that may point to the origin of propensities toward interactive conflict and exploitive exchange, on the one hand, or interactive harmony and fair exchange, on the other.

Mothers pushed beyond the limits of their PI may become increasingly reactive and abusive toward their young (see *Maternal Mistreatment* in Chapter 8). In a study by Scott and Fuller (1965), canine mothers and offspring were kept together until week 10 under relatively austere conditions of close confinement. This rearing practice may have been highly stressful for both mothers and offspring, perhaps accentuating the effects of prenatal stress on the emotional reactivity of the puppies and explaining the high level of agitation and aggression exhibited by mothers toward offspring (Rheingold, 1963). On the other hand, removing puppies too early from the mother may result in lasting impairments diminishing the offsprings' ability to achieve autonomic balance.

In any case, disruptive influences stemming from maternal mistreatment may exert profound and lasting adverse effects on a dog's ability to cope adaptively with complex social demands. However, the same flexibility that makes a puppy vulnerable to destructive influences also makes it highly resilient and responsive to protective influences, perhaps helping to explain the apparent lack of significant maternal effects shown by German shepherd dogs in a recent study performed by Strandberg and colleagues (2004). Whereas exposure to inescapable aversive stimulation shortly after weaning profoundly disturbs adult escape behavior, exposure to controllable aversive events early in life appears to have an immunizing effect against the adverse effects of inescapable aversive events in adulthood (Hannum et al., 1976). How a puppy is treated in the home ultimately seals its fate by either accentuating problematic aspects of developmental programming or by providing it with social and environmental conditions that promote compensatory adjustments conducive to an adaptive coping style and allostasis—*stability through change*.

Attunement, Attachment, and the Human-Dog Bond

According to the affect-attunement hypothesis, dogs and people relate by feeling their way through exchanges and by shifting arousal and output to match the emotional intensity, duration, and shape of the partner's reciprocating actions. The mutual appreciation or sharing of attention, intention, and affective states is marked by the emergence of an interactive attentional nexus and an allocentric relational space within which human and canine partners build complex predictive relations that serve to synchronize arousal and affective states. From a foundation of care relations mediating autonomic attunement, the dog shows an increasing appetite for socially mediated and shared experiences with others. When facing problems or circumstances evincing difficulty or uncertainty, dogs, like infants studied by Stern (1985), may look toward the social partner for "affective content, essentially to see what they should feel, to get a second appraisal to help resolve their uncertainty" (132). The dog's ability to grab and steer the human partner's attention to the location of out-of-reach toys or food reflects a capacity for relating to the other allocentrically, indicating the operation of a cognitive functions that enable the dog to appreciate the perspective of the partner relative to objects of interest to the dog. Affect attunement is commonplace in the interaction between people and dogs (Finck, 1993), especially in the context of caregiving and play exchanges. Affect attunement occurs

when a partner's actions convey the feelings of a shared affective state, and it serves to focus attention on the "quality of feeling" that underlies expressive behavior: "Imitation renders form; attunement renders feeling" (Stern 1985:142).

Affect attunement gives social interaction a quality of sharing an experience and existence that stands outside of oneself. The personal nature of attachment entails that social transactions be tagged with unique social and contextual identifiers. Only exchanges with a specific individual can be encoded and stored in that person's social account, so to speak. Attunement imbues attachment relations with an implication of *responsibility* to the other, as one might feel responsible for how the dog feels and then adjust exchanges to compensate, as needed, to produce affective shifts conducive to a more desirable state, that is, to protect and care for it. As such, the affective changes associated with attunement dynamics that promote social and place attachments have the ontic property of belonging to the other who has an *identity*. To attach is to belong and incur an obligation to care for and to protect the interests of the attachment partner (loyalty). These attachment and attunement dynamics set the framework for many of the benefits of dog ownership as well as potential adjustment problems. Interestingly, when reminiscing over a previous family dog, many dog owners are apt to tell stories that illustrate the belongingness qualities of the attachment by referring to extraordinary caregiving behavior, fidelity, and heroic stories involving the protection of children.

As the result of the autonomic and affective attunement associated with the integration of secure attachments, a bond of belongingness is formed that links the dog and family together to *share* a secure living space held in a common trust (see *Social Spaces, Frames, and Zones* in Chapter 8). Secure social and place attachments shape a dog's identity into one who belongs as an object of care and protection. Social exchanges operating under the modulation of competent attunement serve to anticipate and match autonomic arousal to prediction-control expectancies, calibrated emotional establishing operations, and goal-directed actions (control modules) that enable dogs to accumulate hedonic value in support of optimistic mood, social attraction, cooperation, play, and the integration of an adaptive coping style.

Opportunity with Limit

Attaining cynopraxic objectives depends on decisive action at the right time (*kairos*). In dog training, the coordination, selection, and timing of social exchanges are critical for success. The notion of kairos goes to the inner nature of such intuitive action and timely exchange. The word *kairos* was used in a variety of ways by ancient Greeks to describe timely action or opportunity. White (1987) suggests that the term was used to refer to the brief moment allowed for a weaver to pass a thread through a gap opened momentarily in the warp of a cloth being woven. In the *Odyssey*, Homer combines this early meaning of kairos with a manipulation of time used by Penelope to postpone the time agreed by her to decide and choose among the suitors. Penelope promised the suitors that as soon as she had finished a shroud that she was weaving for Odysseus' father that she would choose a new husband. But the promise was only a ruse to gain time, since at night she undid the work she accomplished during the day. A symbolic implication of her trick is that placing a thread through the kairos advanced time and pulling the thread out again held time back, at least with respect to the timing of the moment for her decision. Eventually, her subterfuge was discovered and the suitors demanded that she now decide and choose. Here, a second meaning of kairos enters the story, bringing the separated husband and wife closer together and setting the occasion for a decisive event. Instead of acquiescing to the suitors' demand, Penelope devised a contest for them to decide the matter of her hand. The challenge required that the winner string Odysseus' horned bow and then shoot an arrow through the hub of 12 axes aligned in a row. Like the passage of a thread through the warp of a cloth, the pas-

sage of an arrow through the opening of the hub of axes aligned in a row is also referred to as kairos (White, 1987), thus linking the two meanings in the critical moment when Odysseus, disguised as a beggar, takes the bow in hand and asserts his status and real identity as husband by stringing the bow and sending the arrow through the kairos. Unbeknownst to her at the time, Penelope's stalling had set the occasion of the contest in synchrony with the return of Odysseus and all that would follow. Having revealed his identity as husband, Odysseus is now united with Telemachus, as father and son, to take the moment of surprise to mete out justice upon the corrupt band of suitors who had invaded his home.

These two meanings of kairos derived from weaving and archery combine a balance of feminine and masculine energy (work or effort) to effect change and restore order and stability to a state of disorder by means of timely action. Thus, the ideal cynopraxic trainer combines the steady patience and intuitive vision of the weaver, on the one hand, and the mental steadiness and strength of the archer, on the other, to act decisively at the best opportunity. The opportune moment is not found by means of spontaneous opportunity-taking efforts, but by acting in accord with limit, by setting the stage, and by letting the opportune moment happen, as exemplified by Penelope's strategic stalling and the circumstances of the contest that she set for the suitors that enabled Odysseus to reclaim his identity heroically as husband and father.

Hitting and Missing the Mark

Social interaction is significantly complicated by the mutual control that social partners have over the moment of exchange and the circumstances surrounding exchange. As a result, social exchange is vulnerable to *tricks* of timing and other efforts used by interacting partners to make exchanges happen in ways that allow them to take an advantage or to engage in preemptive social strategies aimed at protecting themselves against the loss and risk associated with exploitive interaction. The result of such interactive subterfuge is mistrust and misattunement, that is, putting the other out of step by concealment and deception, much as Penelope manipulated the exploitive and obtrusive suitors by her clever ruse. The process of adaptive optimization depends on the reciprocal give and take of opportune moments for attaining reward while staying within fair-play limits to keep the exchange going and thus opening a *social space* of interactive possibility expanding under the pressure of complementary power and freedom incentives. Symbolically, the forces at both ends of the bow must be applied in equal measure to send the arrow straight to the mark. For social exchanges to resonate autonomic nodes conducive to attunement and interactive harmony, they need to be perceived as fair and rewarding. Just as the archer must master the art of letting the bowstring jump with a surprise from the fingers, there is a surprise element that enables social exchanges to *hit the mark* (tychon); that is, social exchanges need to be made at a propitious moment with an element of surprise to arouse interest and to promote learning.

The social skills and confidence acquired in resolving interactive conflict naturally involve attunement dynamics compatible with mutual appreciation and interactive harmony. With improving social skills and confidence, a dog is empowered to pursue a wider range of cooperative projects with its owner in pursuit of freedom incentives. Social exchanges that hit the mark promote enhanced awareness (attentive mindfulness), secure attachments, mutual appreciation, and interactive harmony. Exchanges that miss the mark (hamartia) promote an imbalance of *opportunity without limit* that generates increasing disorder and impulsivity (big-bang effect), whereas exchanges promoting an imbalance of *limit without opportunity* are prone to mediate behavioral reactivity and rigid inhibition (black-hole effect). A persistent failure to engage in fair exchange elevates social distress and promotes conflict monitoring, incompetence, instability, and a state of persistent autonomic misattunement. The

resultant reactive coping style is hypothesized to underlie a wide gamut of social adjustment problems.

BIG BANGS AND BLACK HOLES: EXTRAVERSION, INTROVERSION, AND DISORGANIZING LOAD

Behavioral adjustments may either hit the mark or miss it. One performing actions that hit the mark depends on experience to learn the most opportune moments (occasion-setting criteria) to act and what to expect as the result of actions, and to tune energy expenditures and preparatory arousal to act in accord with those expectancies. Behavioral adjustments are said to *hit the mark* when expectancies, preparatory arousal, and action modes promote social exchanges conducive to reward, autonomic attunement, secure attachments, and an adaptive coping style. On the other hand, a failure to attune arousal and action readiness in accord with reliable predictive information, causing a dog to motivationally overshoot or undershoot the mark or miss the right opportunities to act, promotes behavioral adjustments that *miss the mark*. Social exchanges that consistently overshoot the mark because of a lack of predictive modulation regulating excitatory arousal and action readiness tend to promote an externalizing (approach) imbalance in the direction of hyperactivity, novelty seeking, and exploitive social interaction. At the other extreme, dogs lacking predictive modulation over inhibitory processes may miss the mark by consistently undershooting the mark because of an internalizing imbalance in the direction of behavioral inhibition, social avoidance, and withdrawal. These inhibited types show caution in response to novelty and an active intolerance for situations that require risk taking. Behavioral adjustments that persistently undershoot or overshoot the mark promote autonomic misattunement and insecure or nervous attachments associated with a reactive coping style.

Theoretically, the viability of an adaptive behavioral system is determined by its potential for correspondence, complexity, and flexibility; that is, its ability to achieve a balance between order and variety while constructing a coherent reality organized to cope with uncertainty and change. Behavior-organizing constraints that limit opportunity and variety are hypothesized to result in a loss of adaptive capacity or *adaptability*. A preoccupation with the familiar and the safe renders a dog vulnerable to the pull of axipetal load. Conversely, systems that fail to limit variety and opportunity tend to become increasing energetic, expansive, and disorderly, showing a preoccupation with novelty and stimulus change (uncertainty) under the push of axifugal load. Where axipetal load is associated with excessive energy loss (drain), axifugal load is associated with excessive energy gain (strain). The drain and strain of load impairs a dog's ability to construct a viable *umwelt* and cope proactively with change. These opposite forms of instability represent the extreme ends of allostatic load, whereby energy is tied up in processes that prevent the dog from organizing predictive relations and change conducive to stability.

Axipetal load mediating unstable introversion (high-approach/low-withdrawal thresholds) appears to reduce prediction error gradually to a negative significance—a negativity bias that degrades a dog's ability to cope with loss and risk proactively. These extreme features of unstable introversion roughly correspond to what Pavlov referred to as the *melancholic* (m) type. An m-type dog treats novel and unexpected change as inherently threatening. As a result, the ability of affected dogs to encode and invest novel social exchange with hedonic value is significantly curtailed. Such dogs only slowly habituate to social novelty and tend toward social inhibition and withdrawal. The effect of internalizing load is akin to an affective black hole, where social space is narrowed and closed under the influence of increasing passive modal activity. Instead of searching for reward opportunities, unstable introverts turn attentional resources toward a heighten vigilance for signals of loss and risk in association with an active disinterest in exploratory activity. The adaptive strength of negative prediction error to conserve energy and to limit loss and risk becomes a significant hindrance when

isolated from the balancing influence of cortical reward and active modal activity. As a result, affected dogs may become increasingly preoccupied with conflict monitoring, compulsive rituals, and autoprotective concerns (see *Attention, Dopamine, and Reward* in Chapter 5).

By contrast, unstable extraverts appear to operate under an opposite bias toward novelty and stimulus change. These dogs, corresponding to Pavlov's *choleric* (c) type, tend to treat stimulus change and novelty as intrinsically rewarding, regardless of predictive significance causing them to rapidly accumulate energy gains that produce a state of externalizing load analogous to the big bang, whereby an enormous amount of energy is expended in the vain pursuit of reward signals. Axifugal load accelerates feed-forward processing in the direction of extraversion (low-approach/high-withdrawal thresholds), simultaneously flattening and stretching out space and reducing prediction error to a positive significance. The stretching out of axifugal social space is correlated with a decline in awareness and attentional tone, behavioral disorganization, and dispersive independence (autonomy). The novelty-seeking efforts of c-type dogs are driven by arousal and energy expenditures that have little apparent relevance for the maintenance of homeostasis and security (comfort and safety). In addition, they are unable to engage in fair exchange or to show affect-attunement behaviors. Although they are intensely aroused by the pursuit of novelty and stimulus change, the hedonic significance of their actions does not rise to the level of awareness, and consequently they fail to encode awareness-dependent expectancies and engrams. Affected dogs treat everyone they encounter with the same energetic and exploitive enthusiasm, making few distinctions with respect to the way they engage insiders and outsiders.

A balance of opportunity with limit is crucial for managing information entropies in the direction of adaptive optimization. Goal-directed actions may successfully open the zona securitas but become increasingly rigid with order if not opened to sufficient opportunity. This pattern of progressive deterioration of adaptability is countered by means of utilizing the "noise" (prediction error) associated with the opening of the zona optimus consisting of modal adjustments to positive prediction error (cortical reward). Adaptive coping skills and the confidence to use them under varying circumstances are integrated by means of positive and negative prediction error in association with emergent power and freedom incentives. The strategy promotes competent skills (power) and freedom incentives sufficient to open and share social spaces consistent with the integration of secure attachments and adaptive optimization.

Autonomic attunement nodes activated around points of conflict alter thresholds controlling approach and withdrawal behavior and thus play a significant role in adjusting arousal and social exchange toward the *central field* (i.e., the point of balance between extraversion and introversion) and the opening of the zona securitas (somatic reward promoting comfort and safety) and zona optimus (cortical reward promoting hedonic value and elation). The adaptive optimization that normally occurs as the result of social exchange regulated by reliable expectancies is largely disrupted by a reactive coping style. Instead of organizing competent exchanges conducive to mutual appreciation, fairness, and interactive harmony, the social styles of c-type and m-type dogs tend to become increasingly impulsive and reactive incompetent. Finally, whereas dogs integrating an adaptive coping style are relaxed and ready in anticipation of rewarding social exchange, impulsive/reactive dogs respond to impending social exchange with preparatory anxious or frustrative arousal in anticipation of interactive conflict, thus mediating a heighten readiness to flee, exploit, or confront in response to social stimuli.

According to cynopraxic theory, both m types and c types are extremes that result from a failure to acquire the necessary autoregulation and awareness needed to integrate an adaptive coping style. Most dogs are distributed along the extraversion-introversion continuum by virtue of attachment and attunement dynamics (relative social attraction and aversion), their history of socialization and

training efforts, their acquired capacities to cope with interactive conflict, and their ability to process somatic and cortical reward competently. Although some individual dogs may closely resemble the extreme m and c types, the vast majority of dogs, under the stabilizing influence of an adaptive coping style and exchanges conducive to mutual reward (e.g., comfort, safety, and surprise) and attunement, integrate a phenotypic balance of extraversion (E) and introversion (I), showing behavior roughly corresponding to Pavlov's *sanguine* (s) types (stable extravert) and *phlegmatic* (p) types (stable introvert). The stable introvert and extravert operate under the influence of activity success within the central field organized around a sanguine-phlegmatic axis. The major difference between s types and p types is their respective sensitivity to signals predicting reward and punishment. Whereas s-type dogs are more sensitive to positive prediction error (better-than-expected outcomes) and cortical reward mediating active modal strategies (testing, searching, and exploring), p-type dogs show a greater sensitivity for negative prediction error (worse-than-expected outcomes) and somatic reward (comfort and safety) mediating passive modal strategies (hesitating, waiting, and ritualizing) aimed at securing comfort and safety while minimizing loss and risk.

In contrast, under the destabilizing influence of misattunement and interactive conflict (e.g., loss, risk, and disappointment), extraverts and introverts integrate reactive coping styles to accumulate destabilizing axifugal and axipetal load, roughly corresponding to Pavlov's c type (unstable extravert) and m type (unstable introvert)—behavioral tendencies conferring an increased vulnerability to impulsive and reactive disturbances, respectively (see *Experimental Neurosis* in Volume 1, Chapter 9). A third temperament variation combines features of both m and c types, referred to as a *nervous* (n) type. An n-type dog shows low reactive thresholds, making it prone to panic and helplessness associated with chronic insolvable conflict. N-type disturbances are characterized by conflict intolerance, compulsivity, and panic occurring under the influence of a *dysfunctional bias* toward change that cause affected dogs to persistently attribute danger and uncontrollability to significant events, even though the events are benign and highly amenable to proactive control efforts. N-type disturbances combine m-type and c-type characteristics along with persistent mood changes combining high levels of toxic anxiety and frustration (dysthymia).

Dogs showing n-type disturbance appear to cope with change through the distortion of a dysfunctional bias of danger and powerlessness that causes them to believe that whatever they do will have little effect on what ultimately happens. In situations involving choices between highly motivated alternatives (flight-or-fight conflict), such dogs are prone to panic (low reactive thresholds) or fall into a state of helpless resignation. Genetic predisposition, prenatal and postnatal stress, abusive rearing practices, and highly emotional social interaction lacking predictability and controllability may contribute to the expression of n-type disturbances. Paradoxically, highly ordered environments and social exchange that encourage excessive dependency and insecure social and place attachments may also impair a dog's ability to cope adaptively with the uncertainty of social and environmental change, contributing to a perception of change as being intolerably risky, unpredictable, and uncontrollable (see *Defining Insolvable Conflict* in Volume 1, Chapter 9). As a result, socially sheltered dogs may prefer insular conditions (e.g., they may "like" crate confinement) and seem most satisfied with rigid and monotonous routines.

The anxious–state arousal of dogs showing n-type disturbances appears to be of a different qualitative order than the stimulus-oriented anticipatory anxiety and bias for signals of punishment shown by m-type dogs or the action readiness and bias for signals of reward shown by c-type dogs. The persistent and conflict-reactive anxiety and anger-reactive responses to frustration associated with n-type dysfunction promote catastrophic conflict, with the affected dog appearing to lose consciousness. The panic behavior characteristic of n-type dogs depends on the predisposing influence of reactive thresholds controlling

the escalating activation of fear and anger. Dogs expressing low flight (fear bias) and low fight (anger bias) thresholds are prone to reactive panic in response to social exchanges perceived as posing an uncontrollable danger. Such dogs may show highly inappropriate and incompetent behavior in response to benign social stressors or impediments to freedom. N-type dogs sometimes show an anomalous intolerance for tactile stimulation, reacting to gentle handling and petting with panic-driven paroxysmal attacks.

Reactive emotional adjustments to change (e.g., depression, anxiety, worry, and panic) are prone to develop under social and environmental conditions perceived by a dog as unsafe and inescapable. According to this hypothesis, the impulsive and exploitive tendencies of the c type, on the one hand, and the anxious withdraw tendencies of the m type, on the other, are the default coping strategies of dogs exposed to situations perceived as uncontrollable, unsafe, annoying, and/or inescapable. The terms *social ambivalence* and *entrapment* are used to refer to these general social and environmental influences promoting a reactive coping style. Finally, stable and unstable orientations to reward (extraversion) and punishment (introversion) may originate in organizational processes first appearing in association with the parent-offspring conflict.

Coping with Conflict

Household social interaction, in all its nuances and refinements, is the result of human and canine adaptations to the competition and possessiveness arising from interactive conflict. Conflict sets the stage for the emergence of both reactive and proactive adjustments, depending on the abilities of the owner and the dog to prevent or avoid conflict when opening and sharing a *social space* (see *Social Spaces, Frames, and Zones* in Chapter 8). Although a dog's control interests are mostly confined to the pursuit of attractive motivational stimuli under a freedom incentive, an owner's control incentives are more often informed by power incentives. The owner may experience a strong sense of failure and inadequacy when unable to limit the dog's undesirable behavior. The loss of control experienced by the owner may heighten aversive feelings of anger and resentment toward the dog while mediating a state of misattunement, marginalization, entrapment, and social ambivalence. Many owners are under the persuasion of bad advice that a dog's conflictive efforts are motivated by a dominance incentive, causing the owner to engage the dog in exchanges that perpetuate and worsen the problems, rather than restoring social attraction and trust.

By necessity, while in pursuit of motivational interests, the dog is forced to negotiate around the owner's interference and control efforts. The attunement and social skills acquired when integrating an adaptive coping style serve to reduce conflict, whereas a chronic history of coercion, exploitation, frustration, loss, risk, and discomfort is likely to attune the dog and its owner to anticipatory expectancies that virtually ensure conflictive exchanges whenever they interact. The anticipation and preparation for conflictive exchange can be turned around and harnessed to cynopraxic objectives by integrating social exchanges with the dog that disconfirms the conflict expectancy. Instead of evoking unfair and conflictive exchanges where reward for one depends on loss or risk for the other, cynopraxic training focuses on restructuring and attuning social exchange toward mutual reward, cooperation, and trust. Social exchanges that satisfy the owner's social control needs (power incentives) while simultaneously gratifying canine seeking needs (freedom incentives) provide a basic structure that enables people and dogs to engage in mutually rewarding social activity.

Social interaction perceived as uncontrollable, unsafe, or biologically unfavorable may promote social and cognitive (attentional) disengagement, lower reactive flight-or-fight thresholds, and cause the dog to become increasingly irritable, intolerant, and reactive to social interference via the activation of a loner-dispersal survival mode. Chronic exposure to an impoverished or threatening social or living space in association with the dispersive tensions generated by an involuntary sub-

ordination strategy (ISS) may gradually exhaust a dog's stress-regulating abilities and sharpen household tensions. The degradation of interactive relations as the result of unresolved conflict may gradually result in exchanges unable to support secure attachments. As a result, the dog may become increasingly reactive toward ambiguous and relatively benign social signals as the emotional regulation afforded by attunement is lost in association with encroaching estrangement and mistrust.

The establishment of organized household relations is rarely achieved without significant interactive conflict along the way. Depending on how interactive conflict is managed, a dog may either adopt a voluntary subordination strategy (VSS) or an ISS (see *Interactive Conflict, Stress, and Social Dominance* in Chapter 7). Psychologically, a dog is organized to predict and control (i.e., manage) social events to exploit them for advantage. Excesses and deficits associated with such management interests are tempered by a sense of fairness, playfulness, and a love of social companionship with people. Under the benign influences of social leadership and the nurturance of a friendly VSS, interactive conflict and reactive tensions are gradually superseded by social attraction, mutual appreciation, and interactive harmony. Social and autonomic attunement serve to align and coordinate the cognitive and emotional processing needed by a dog to pursue its private interests competently while preventing, limiting, or resolving interactive conflict, as needed to consolidate social relations. Dogs adopting a VSS tend to become increasingly relaxed and confident while organizing an adaptive coping style and integrating secure social and place attachments. The pursuit of private interest becomes a public or household concern when it gives rise to competition and possessiveness aimed at *getting* and *keeping* some valued resource at an expense or harm to others sharing the home.

To achieve a state of relative harmony and peaceful coexistence, a dog must be compliant to owner control efforts, but the owner must in turn be able to compromise and to share the living space with the dog (see *Unilateral, Bilateral, and Pluralistic Relations* in Chapter 8). Most puppies and dogs come into the home as default subordinates but lack knowledge of the specific rules for sharing in household activities and resources. Subsequent interactive conflict results when the puppy or dog attempts to engage in reward-seeking activity in ways that conflict with owner power incentives. A puppy is best introduced into the home by means of identifying points of conflict and converting them into points of mutual reward and interactive harmony. Interactive compliance training (ICT) plays a critical role in facilitating social adjustments conducive to a VSS by means of conflict-resolving interactions. ICT serves to consolidate and refine the owner's control interests while the dog learns how to control valued resources and activities without engaging in disruptive competition. These rules are taught in process of integrating flexible *ascendant* and *descendant* relations based on a principle of fairness and pluralism, whereby sharing the living space is at the owner's consent and ability to assert veto power and *default dominance*, if necessary.

In the process of cynopraxic training, the owner and the dog shift from a reactive orientation fueling interactive conflict to a proactive orientation or *adaptive coping style* by means of social exchanges that optimize fair exchange and mutual reward, enhance the dog's ability to pursue power and freedom incentives in the absence of reactive arousal and interference, and integrate secure social and place attachments. Cynopraxic training theory postulates the following working hypotheses and claims regarding the integration of an adaptive coping style:

1. The loss and risk resulting from interactive conflict are experienced as emotional distress (anxiety and frustration) that preemptively conditions social approach with a negative efficacy bias (low-power orientation) in anticipation of conflictive exchange.
2. Emotional distress provides an aversive incentive conducive to the integration of proactive adjustments organized to prevent or avoid conflict.
3. The integration of prediction-control expectancies and calibrated emotional establishing operations organized in accord with fair exchange and reward promotes mutual attunement, causing

social approach to become increasingly relaxed and expectant of friendly exchange under the preemptive influence of a positive efficacy bias (high-power orientation).
4. Attunement coordinates energy-state changes via calibrated establishing operations and control expectancies to promote mutual reward and fair exchanges incompatible with conflict.
5. Chronic interactive conflict results in mutual powerlessness, entrapment dynamics, social ambivalence, and the activation of autoprotective modes, whereas conflict resolution promotes mutual empowerment, freedom, and secure attachments promoting mutual comfort and safety, mutual appreciation, and playfulness.
6. Cynopraxic training converts the energy diverted into conflictive exchange and resulting in homeostatic distress (energy loss) and turns it toward energy-conserving exchanges organized to resolve or prevent conflict in process of producing energy gains and homeostatic balance.
7. Exchanges yielding transactions producing energy gains are hypothesized to encode attunement via the calibration of emotional establishing operations. The preattentive comparator processing of energy gains scaled to hedonic value gives rise to a heightened state of awareness of pleasure. As such, the hedonic value attributed to energy gains and losses is an interpretive function or algorithm converting energy gains derived from better-than-expected outcomes into experiences and memories having the significance of pleasure (positive hedonic value), whereas the energy losses representing worse-than-expected outcomes are encoded into experiences having the significance of displeasure (negative hedonic value).
8. The energy gains obtained as the result of preventing and avoiding interactive conflict provide the trainer and the dog with the enhanced awareness and capacity to encode the significance of social exchange as experiences and memories needed to foster the social skills, autonomic attunement, and confidence (power) to engage in mutually rewarding cooperative projects and ventures. The power derived from the energy gains stemming from the resolution of conflict is integrated into predictive relations that open social space under the expansive dynamics of a freedom incentive. In contrast, the power lost due to energy losses stemming from interactive conflict results in the contraction of predictive relations, the closure of social space, and the accumulation of axipetal and axifugal load collecting in the opposite directions of unstable introversion and extraversion.
9. The effective resolution of conflict depends on the initiative and leadership abilities of the trainer to organize and guide mutually rewarding exchanges based on a principle of fairness (the golden rule), compromise, and cooperation around situations previously generating conflict.
10. Learning to prevent and resolve conflict results in mutual empowerment and liberation, with the dog and the trainer integrating the skills and the confidence needed to obtain mutual reward in the context of fair exchange and cooperation, as exemplified in play.
11. The translation of conserved energy into positive mood, mutual attunement, and stable predictive relations serves to promote social attraction and to open a social space within which people and dogs integrate secure social and place attachments.
12. Power and freedom incentives are most fully expressed in the form of affectionate play.
13. An attentional nexus conducts exchanges between the trainer and dog around points of common interest in the process of activating the SES and mediating autonomic attunement. The autonomic attunement and social awareness resulting from the activation of the SES simultaneously serve to disengage disruptive autonomic arousal driving conflictive control incentive and vectors, thereby enabling the trainer to turn his or her attention on the dog (and vice versa) as an object of affectionate appreciation and play.

14. With the emergence of power and freedom incentives focused on the mutual integration of social skills and confidence to avoid conflict, a principle of fairness and social codes naturally emerges to facilitate social exchange and attunement dynamics incompatible with conflict.
15. The mutual reward mediated by fair exchange serves to promote attunement, heightened awareness, and the joy arising from mutual appreciation and interactive harmony, as exemplified in affectionate play.

Under the influence of social ambivalence and entrapment, dogs appear to cope by withdrawing from the insecure/nervous attachment object, on the one hand, and by increasing their dependency on locations having conditioned associations with security (comfort and safety), on the other. Building social tensions (e.g., anxiety, frustration, irritability, and intolerance), impulsivity, lowered reactive thresholds (e.g., fear, anger, and panic), a preemptive negativity bias causing dogs to anticipate conflict with the approach of the owner, and the breakdown of social communication set the stage for reactive and impulsive autoprotective behavior. In addition to the retraction of the SES, a key factor in this process of estrangement and marginalization appears to involve the diversion of attentional resources to conflict monitoring, and *tuning out* the ambivalent attachment object. According to cynopraxic training theory, attention and impulse control are intimately interconnected and interdependent upon each other.

The disengagement of attentional resources combines synergistically with social withdrawal to imperil dogs with autonomic dysregulation and vulnerability for impulsive and reactive adjustments. These hallmarks of a nervous attachment make it difficult for dogs to experience coherent feelings of social security and belongingness in the home. The pervasive cognitive and emotional perturbations of chronic interactive conflict substantially disrupt a dog's ability to selectively attend to and decode the transactional significance of social exchanges with family members and to cope proactively with the most ordinary and benign social stressors. The ensuing dispersive tensions and marginalization may mediate an untenable insider-outsider orientation between the dog and the family members. In essence, the dog appears to undergo a process of estrangement and dissociation that gradually causes it to experience family members as "super pals" (tuning in) or as strangers and threats (tuning out), making them fit targets for impulsive attacks. If left untreated, such dogs not dispersed by rehoming or relinquishment, much as a captive wolf, unable to freely disperse or integrate is badgered and finally killed, may face a predicament of intensified social ambivalence, entrapment, and punishment, until at last the intolerable situation is disposed of by means of veterinary proxy.

Restraint, Unavoidable Aversive Stimulation, and Stress

Most dogs express flexible antistress and antiaggression capability but not in equal measure, with some breeds, on average, showing a greater proclivity toward reactive behavior than others (Malhut, 1958). Also, there is tremendous variation among individuals within the same breed that affects fearful behavior. In addition to differences affecting reactive thresholds in response to innocuous novel stimuli, Malhut found that breed-related differences affected the sort of coping style exhibited by the dogs. Corson and O'Leary Corson (1976) have also reported significant individual variation in the way dogs cope with isolation, physical restraint, and unavoidable electrical stimulation. Certain dogs—notably those belonging to herding, spaniel, and terrier breeds—show an ensemble of reactive behavioral and physiological changes when exposed to psychological stressors. These reactive dogs, which the researchers refer to as *antidiuretic* or low-adaptation types, exhibit a persistent pattern of increased metabolic activity and autonomic activation—physiological changes that typically occur in association with the sympathetic arousal and muscular exertion used to fight off or escape from a serious threat or

challenge. In contrast to the reactive pattern exhibited by antidiuretic low-adaptation dogs, other dogs showed a more passive coping style in response to unavoidable aversive stimulation and restraint. Many of these high-adaptation or *diuretic* types showed a transient antidiuretic response that diminished after several sessions of conditioning, whereas other dogs (most notably beagles and other hounds) showed little sign of disturbance in response to the stressors.

The antidiuretic stress response is hypothesized to be the result of an emotional conflict consisting of a strong incentive to escape coupled with an inability to break free of the Pavlovian-restraint apparatus. The ensuing conflict, escalating anxiety, frustration, and defensive arousal may result in elevated body temperature and various compensatory thermoregulatory activities aimed at restoring thermal homeostasis, including hyperpnea (panting), elevated heart rate, increased respiration, profuse salivation, high levels of plasma AVP (antidiuretic hormone), and reduced urine production (Corson and O'Leary Corson, 1969):

> In spite of the inability of the antidiuretic dogs to engage in fighting or to escape, the physiologic reactions of these animals appear to be those associated with severe muscular effort. We postulated that these dogs pant in order to dissipate the extra heat production associated with anticipatory responses to muscular effort. The excessive salivation serves to provide the water required for evaporative cooling during the hyperpnea. The antidiuresis serves the purpose of conserving water by the kidneys so as to make the water available for the increased secretion of saliva. (155)

The researchers found that after an avoidance contingency was introduced that allowed the dogs to avoid the electrical stimulus, many of the reactive antidiuretic dogs showed a marked shift toward normalization of autonomic tone and balance, but some of the dogs failed to adapt despite the most thorough training efforts (Corson et al., 1973). Among these nonresponders, a subgroup of antidiuretic dogs persistently reacted to restraint in the Pavlovian stand, with some chewing through harnesses and cables in their frenzied efforts to escape. The emotional effects of restraint were especially pronounced when the experimenter left the room, which suggests that the experimenter's presence exercised a significant stabilizing effect. The reactive behavior in response to restraint described by Corson and colleagues as hyperkinetic is reminiscent of a dog described by Pavlov that showed a similar pattern of reactivity and profuse salivation when restrained. Pavlov attributed the persistent autonomic reactivity shown by the dog to a thwarted *freedom reflex* (Pavlov, 1928) (see *Liddell: The Cornell Experiments* in Chapter 9, Volume 1). The descriptions by Pavlov of the dogs behavior seem consistent with the classical signs of separation distress/panic, representing the earliest known description of such disorder in dogs:

> One of our many dogs, used during the past year for the study of acquired, or conditioned, salivary reflexes exhibited especial characteristics. This animal when first used by us for experimentation gave, when placed on the stand, in distinction from all other dogs, a spontaneous and constant secretion of saliva during an entire month. This, of course, rendered it unsuitable for our experiments. This secretion of saliva is as we know from previous observations, dependent upon a general excitation of the animal, and is usually accompanied by dyspnea. Such excitation of the dog is evidently analogous to the state of excitation in the man, where it is manifested, however, by sweating instead of salivation. A short period of such excitation is seen in many of our dogs during the first experiments with them, and especially among the untamed and wilder of them. On the contrary, though, the dog in question was very tame and quickly became friendly with us all. That made it even more strange that for a month the excitation in the experimental stand did not diminish to any degree.…The spontaneous salivary secretion continued, and gradually increased with each experimental séance. Also the animal constantly moved, struggling in every possible way in the stand, scratching the floor, and pulling and biting at the frame, etc. (283)

Months of intensive counterconditioning failed to calm the dog and hypersalivation increased over time. Only after 4 1/2 months of isolation in a separate cage did the dog finally stabilize and become amenable to han-

dling and experimentation. Interestingly, in a language reminiscent of Nietzsche's "instinct for freedom" and slave morality, Pavlov contrasts the "reflex to freedom" with a "reflex of slavish submission," thereby placing the etiology of such behavior into the context of social imperatives and dialectics consistent with the interactive dynamics believed to contribute to the expression of nervous and insecure place/social attachments. Freedom of movement is a precondition for a dog to act effectively in accord with control and power incentives. As such, the loss of freedom associated with excessive crate confinement results in a significant loss of reward, as it forcibly separates the dog from the means needed to produce reward via the control of attractive and aversive motivational incentives. As a result of the combination of social isolation and loss of freedom imposed by confinement, the dog may experience a persistent state of internal conflict combining heightened anxious arousal and frustration.

The potent effects of crate confinement on the inhibition of urine production may stem, in part, from the release of AVP triggered by restraint and isolation of crate confinement. Corson (1966) reported that dogs living in small cages were prone to develop various nervous behaviors, including antidiuresis, reduced appetitive drive (e.g., anorexia and adipsia), and avoidance of social novelty (e.g., running away from strangers). QOL enhancements, which included housing the dog in a room and providing it with daily walks, helped to eliminate these aberrant behaviors. Social abuse, isolation, and restraint stress may underlie some of the persistent learning deficits exhibited by dogs exposed to excessive isolation and crate confinement. For example, increased opioid activity resulting from aversive interaction and chronic restraint stress may impair memory and associative learning capacities (Westbrook et al., 1997; McNally and Westbrook, 2003; McNally et al., 2004). Also, chronic stress causes glucocorticoid-mediated disturbances in cortical and mesolimbic DA reward pathways, and degrades cholinergic hippocampal circuits that preferentially mediate spatial and contextual learning.

These various stress-related changes in combination with autonomic imbalance and a concomitant rise in CRF, AVP, and NE may help to explain the crate-dependent aggression exhibited by some dogs. When restrained, crate-conditioned triggers may mobilize autonomic state changes and phase shifts in the direction of autoprotective action modes. When removed from the crate, these dogs appear to shift rapidly out of the dysregulated state into a state of excited arousal facilitating exploitive and impulsive exchanges but do not show any evidence of hostility. A similar pattern of arousal and dysregulation is predictably exhibited by some dogs while on leash, causing them to show an escalating state of aggressive arousal toward other dogs until they are released, whereupon they may rapidly (but not always) shift into a state of autonomic regulation conducive to exploitive and intrusive play.

A linkage with social isolation in the development of aggression has been frequently observed in the laboratory. Lagerspetz and Lagerspetz (1971), for example, found that mice selected for aggressiveness and nonaggressiveness for 19 generations showed significant variability with respect to learning aggression and their ability to cope with isolation stress. In one experiment, male mice were taken from these two groups at weaning and housed for several months in small groups. At month 8, mice selected for aggressiveness were housed in separate cages and tested on a weekly basis for 2 months. When tested at 8 months (prior to the first week of isolation), well-socialized aggressive mice showed no aggression when put in a novel cage with a nonaggressive mouse. After only 1 week of isolation, however, these same mice showed a rapid increase in aggressive reactivity that remained at a high level during the 8-week testing period. Even mice selected for nonaggressiveness showed increased aggression after 2 weeks of isolation. The authors emphasize the importance of social punishment as the decisive factor limiting aggressive impulsivity. As the result of retaliation and defeat consequent to aggressive actions, socialized mice appear to learn how to regulate their agonistic impulses. In the absence of punitive social

feedback, the predisposition toward aggression is heightened, a finding also reported among Hereford bulls (see *Play, Social Engagement, and Fair Play* in Chapter 8).

Paradoxically, after months of crate confinement, the crate may become a potent source of autonomic regulation promoting relaxation and sleep. Many dogs show a strong preference for sleeping in the crate and, if denied access to this "safe haven," often show signs of heightened autonomic distress and an inability to relax until they are put in their "den." Such dogs frequently show unproductive exploratory pacing, persistent panting, increased gut motility, and other signs indicative of autonomic dysregulation—all while the owner is nearby. When given access to their crate, these dogs immediately regain their composure, perhaps as the result of place attachments and security that they associate with the location. The behavior of these dogs is consistent with the distress behavior exhibited by dependent and insecure dogs when left alone. These sorts of observations have convinced many advocates of long-term cage and crate confinement that dogs really like being crated day and night—a bizarre belief that is used with great effectiveness on the low-power owner in order to help assuage guilt and rationalize excessive confinement of the dog. That a dog should prefer a state of social and physical privation and loss of freedom to the security and enjoyment of close company with family members is more rightly interpreted as evidence of social pathology than a healthy preference. The bond and QOL deficiencies evident in such a "preference" for social isolation and loss is antithetical to the goals of cynopraxic training and therapy (see *Mechanical Suppression of Behavior*).

Attentional Nexus, Allocentrism, and Attunement

The opening of an attentional nexus implies an appreciation of the other's viewpoint, that is, an allocentric orientation. The integration of an allocentric perspective translates the human umwelt into messages sensible to the canine umwelt and vice versa. Attunement is consequent to affective inferences (anthropomorphism) and attributions concerning the nature of the dog's doings. In fact, anthropomorphism plays a prominent role in the process of constructing a viable interface of affectionate and flexible exchange between people and dogs. These anthropic attributions and valuations provide a profoundly rich and complex cultural backdrop from which to receive and transmit affective information. Attunement dynamics are integrated at an early age, beginning with the undifferentiated approach behavior of neonatal puppies in search of contact comfort, appetitive gratification, and thermoregulation from the mother. These early protobehaviors are gradually incorporated in complex rituals used by dogs to negotiate conflict and allelomimetic behaviors. Among puppies, social facilitation invigorates the coordinated pursuit of common interests, at least until the activity threatens to escalate into conflictive exchange, whereupon social inhibition is evoked (Scott and McCray, 1967). These early attunement dynamics serve to promote social enthusiasm while curbing motivational momentum that might lead to overt antagonism.

Attentional Nexus, Social Communication, and Control

Domestication has significantly improved the dog's capacity to cope with stress and social uncertainty via the evolution of antistress and antiaggression capacities, enhanced attention and impulse-control abilities, exchange-mediated autonomic attunement, and the integration of a sophisticated SES consolidating these various changes (see Porges, 2003). As a result, the dog's ability to explore and rapidly establish social relations under a positive expectancy of reward is generally ascendant to negative expectancies and the social aversion associated with dispersion and entrapment dynamics. Dogs appear to respond to the presence of a person as an intrinsically rewarding object, with social contact possessing both incentive significance and hedonic value. For many dogs, petting is not only calmative but is also restorative in nature (see

Affection and Friendship in Volume 1, Chapter 10). The mere presence of a person nearby activates antistress capacities that enhance a dog's ability to cope with pain and stress. In addition to generally enjoying human social contact, dogs have evolved a proactive sociability that enables them to smooth over social tensions with conciliatory exchanges before they escalate into conflict. In short, dogs are developmentally organized to attune and commune with people. Along with these various changes affecting canine sociability and emotional adaptability, dogs appear to have acquired complementary sensory and cognitive capabilities that enable them to socially engage and communicate with people and to follow human instruction (Warden and Warner, 1928; Szetei et al., 2003).

Some authors have emphasized that the dog's enhanced abilities to initiate communicative interaction with people is due to an enhanced capacity for social gazing (Miklosi et al., 2003), perhaps augmenting the dog's abilities to decipher the significance of human social signals (see Hare et al., 2002). McGreevy and colleagues (2004) report that brachiocephalic breeds tend to concentrate receptor ganglion cells around the central area, in contrast to dogs with elongated muzzles that tend to express a visual streak (see *Orienting, Preattentive Sensory Processing, and Visual Acuity* in Chapter 8). Consistent with the aforementioned social-gaze hypothesis, these authors speculate that a genetic trend toward a frontal placement of the eyes and shortening of the muzzle might have developed as the result of selection pressures favoring visual capacities that enabled dogs to focus on the human face.

Relevantly, Viranyi and colleagues (2004) have observed that canine begging behavior is preferentially directed toward an attentive person rather than a person looking away from the dog. The authors suggest that such preferences might reflect an appreciation of human attentional cues insofar as they help to improve the success of instrumental food-sharing projects. The authors also found that a dog's ability to perform a basic obedience exercise ("Down") in response to a recorded command varied depending on whether the owner was out of sight, faced the dog, turned away, or faced another person while giving the command. The best performance was obtained when the owner gave commands while facing the dog, followed by commands given as the owner turned his or her head away from both the dog and person. The dog showed an equal disruption of performance when the owner was out of sight as when facing a nearby person. The authors interpret these findings as evidence of special attention-dependent capabilities. However, since most dogs can be trained to lie down rapidly and consistently in each of the previously mentioned stimulus and contextual conditions, and given the limited controls used in the experiment, it would seem extremely difficult to sort out what is attributable to the effects of owner-training skills versus the effects of special cognitive abilities expressed by dogs as a group. Although some acquired skills appear to depend on the help of directional cues for a dog to perform well, others do not. Warden and Warner (1928) explored many of these problems in the case of the dog named Fellow, finding that tasks such as sitting and lying down on command were not appreciably affected by changes in attentional focus or directional cueing, whereas routines that required the dog to move toward places or to select objects were much more dependent on attentional and directional cueing (see *Nora, Roger, and Fellow: Extraordinary Dogs* in Volume 1, Chapter 4).

Several authors have hypothesized that dogs have acquired, as the result of domestication, unique capacities for interpreting and responding to human directional cues. The dog's ability to translate directional information derived from gross and subtle pointing and indicating movements is well developed (Hare and Tomasello, 1999), seeming to surpass the abilities of chimpanzees and wolves (Hare et al., 2002). Although dogs are undoubtedly responsive to human deictic (pointing) signals, nonverbal directive signals, and social gaze, capabilities that trainers have fostered for centuries, it is not clear that this capacity is the result of special cognitive adaptations. To take an extreme example, unstable pointer dogs would likely show significantly less responsiveness to directional gaze and pointing cues than would stable counterparts,

not because pointers lack such ability but because preemptive reactions toward humans prevent them from showing that they have it. The ability of such dogs to use directional signals in appropriate ways only becomes fully evident when training them to hunt, as demonstrated by McBryde and Murphree (1974). In addition to training, the participation of an eager and playful pointer appeared to prime and attune an unstable pointer with arousal and direction that helped to break the spell of cataplexy. Once in their umwelt, the unstable pointers rapidly learned to show and respond to pointing signals:

> The performances of both nervous and normal dogs were quite comparable on an overall basis. The nervous dogs scored about as well throughout and just as well as the normal subjects on their last two trials which were intended to evaluate each dog's final abilities after rehabilitation. On an individual basis some of the nervous dogs did better than the normal controls. (81)

Despite significant changes away from the laboratory, their confident and human-friendly behavior did not generalize back to the laboratory, where they rapidly reverted to the same unstable and nervous behavior shown before field training. Apparently, in the absence of natural stimuli promoting drive arousal conducive to hunting activity (prey-seeking action modes and modal strategies), these dogs get *stuck*. The disorder does not appear to be primarily caused by fear or an aversion to novelty, since nervous dogs rapidly lost most of their timidity and could tolerate close human contact and the blast of a shotgun while hunting. Instead, these dogs appear to be affected by an overspecialization of function genetically encoded around hunting. Perhaps more fundamental, though, is the presence of a genetic defect affecting parasympathetic braking and accelerator functions. The ability to attenuate and accelerate arousal competently while remaining in a parasympathetic mode of activation may be an important aspect of domestication and herald the emergence of the canine SES (Porges, 2003).

Thus, individual differences affecting the dog's arousability and sociability (approach and withdrawal thresholds), motivational interest (incentive and hedonic value) in the reward object, susceptibility to conflict and distress during testing (anxiety and frustration thresholds), age, and relative social dependency (see Topál et al., 1997) would likely generate significant variability into any cognitive test relying on social and motivational variables not equally distributed among experimental subjects. These various influences represent additive confounds that have long been recognized as obstacles to the scientific investigation of animal cognition and continue to plague it with ambiguity.

To take an experimental example of the sort of risks involved in cognitive theorizing, Triana and Pasnak (1981) tested 32 cats and 23 dogs in eight standardized object-permanence tasks using a soft toy as the objects. Although dogs and cats completed some of the tasks, they consistently failed (with the exception of one dog) to solve the invisible displacement tasks. In a second experiment, two additional naive dogs and three cats were tested, but this time the researchers used savory treats and chunks of hamburger as rewards. Under the influence of enhanced motivation, the two dogs and three cats completed all eight of the tasks in a "logical manner." Now, if one took the results of the first test as a true estimate of canine and feline cognitive abilities, the interpretation would be consistent with the results of the experiment but wrong with respect to the dog's actual object-permanence abilities. Further, the second experiment might be erroneously interpreted as evidence of extraordinary cognitive skills, but neither experiment actually says much about cognition per se and instead underscores the reality that cognition and motivation are not easily dissociable, especially when the one variable is manipulated to test the other. Consequently, object-permanence tests employing such things as rubber toys may not measure the extent of cognitive capabilities as much as they measure a dog's motivational interest in getting the object concealed and their willingness to invest the attentional resources and energy needed to encode a working memory of it.

Pointing at a container concealing a treat is not a neutral deictic signal but may also carry the added significance of a command; that is, the directional cue may signify a demand "Go

there"—not merely indicating where the food is (i.e., a "There it is" signal) but carrying the added implication of a dominance imperative. Further, standing behind and pointing directly over an object may not necessarily be interpreted by the dog as a "Here it is" signal or a "Go there" signal but rather may project a "This is mine" significance. Accordingly, standing over and pointing at an object while repeatedly glancing from it to a dog should cause many dogs to withdraw from the object. In fact, many dogs can be caused to avoid forbidden objects merely by alternating glances toward the dog and back again while intently staring and pointing at the object. The effect can be very strong and appears to accumulate over repeated trials and may be augmented with auditory orienting signals. With regard to such dogs, learning to approach and take objects that are pointed at from above may be contraprepared. Dogs rarely, if ever, relinquish food to other dogs by dropping it and then glancing at the other dog and staring at the object to indicate that the other dog should take it. Such social signals when they do occur more likely carry an opposite significance, that is, represent a dare or challenge. Typically, when dogs give up objects, they indicate this intent by moving away from them. They are not particularly well adapted to engage actively in showing behavior with conspecifics when it comes to highly valued objects. The "Go there" imperative should also be subject to the influence of individual differences. In all of these cases, extraverts (with low-approach/high-withdrawal thresholds) should outperform the introvert (with high-approach/low-withdrawal thresholds).

The finding by Hare and colleagues (2002) that puppies perform the object-choice task fairly well from the start and that the "skill" does not appear to be much affected by rearing or social exposure to people seems inconsistent with the findings of other authors (see Soproni et al., 2001). The lack of effect resulting from rearing and social experience is especially puzzling given the findings reported by Topál and colleagues (1997), who found a strong correlation between the number of glances toward the owner, social dependency, and reduced problem-solving efficiency. Of course, one way to explain Hare and colleagues' findings is the possibility that the learning needed to decipher the significance of directional cues is epigenetically articulated into puppy behavior at an early age. The notion that complex social skills might emerge in the context of early ontogeny should not come as any surprise, nor should its significance be downplayed.

The social-cognition hypothesis faces other more formidable problems when the results are judged in the light of prior experimental work performed in Konorski's laboratory. In a series of delayed-response experiments performed by Lawicka (1959), dogs were taught a 3-choice response that depended on the directional information provided by a 3-second orienting signal, a buzzer emanating from one of the different locations. After a variable duration delay, with or without intervening distractions (e.g., feeding the dog or taking the dog from the room), the dogs were released to choose. Dogs readily learned to make the correct location-choice responses, despite distractions, long delays, and even after falling asleep. In one dog, delays of over 18 minutes proved of little difficulty, with the dog making no errors in 7 trials (see Lawicka, 1959:202). Thus, the dogs did not depend on body orientation, but appeared rely on an oculocentric map to orient toward the signalled location.

Lawicka's findings suggests that the distance between the boxes from where the buzzer emanated appeared to enhance the integration of predictive information into the canine localizing map. When the boxes were widely spaced apart (e.g., over 12 feet) the dogs perform the location-choice task after long delays with few errors, whereas when the boxes are placed close together the delay abilities of the dog are "drastically reduced." These observations are extremely interesting since they appear to suggest that delayed response capabilities are partially dependent on the spatial distribution of reference points scaled to coordinate action to locate stationary objects concealed at some distance away, perhaps revealing significant features of the canine umwelt. One might expect that moving objects, including those in slow motion, would not yield lasting memory traces of a

location but might yield predictions concerning the future location of the object based on a trajectory, speed, and prominent terrain markers. Accordingly, allowing the dog to briefly (2 seconds) observe another dog walk by in front of the house before closing the door and taking it to another room for a brief delay, reveals that the dog immediately angles off in the direction last observed, even though, in fact, the dog was immediately turned about and walked in a opposite direction after the door was shut.

Lawicka and Konorski (1959) observed that prefrontal dogs treated directional cues much like a pointer orients and freezes its focus and posture in the direction of the cued location, thereby depending on proprioceptive and vestibular signals to hold on point. discounted the value of such responses with respect to cognitive function, however, referring to them as "pseudo-delayed," since the arrangement could not exclude the confounding possibility that the dog was relying on propioceptive and vestibular propioceptive and vestibular signals when orienting and making location-choice responses. In addition, Konorski and Lawicka (1964) found that dogs suffering prefrontal lesions are still able to correctly follow directional signals, so long as the signals were closely tied to the object's location and that the dog was released during or shortly after the directional cue was discontinued. Now, if dogs with massive prefrontal lesions can "solve" such problems by remaining physically oriented on the location during the delay period, it makes it difficult to assume that the performance is strictly speaking of a cognitive nature. These findings are bad news for the social-cognition hypothesis. If a dog without a functional prefrontal cortex can perform the requisite orienting and approach response, then the social-cognitive hypothesis is falsified, that is, the action might not depend on cognitive ability at all.

In order to overcome these confounding influences, delayed-response procedures can be designed with built-in interference effects that filter out positional information, e.g., the dog is turned around, distracted with food or petting, and even momentarily taken away from the starting point before being released again to choose. Interesting work performed by Nippack and colleagues (2003) appears to have avoid many of these obvious experimental pitfalls while exploring the effect of delay on latency and response accuracy.

Sensitivity to Human Attentional States

One might expect that under circumstances in which deictic signals result in interference or exploitation by an observer that a dog might employ gaze amd directional cues to turn the other's attention away from the location or object of interest. The results of a study by Call and colleagues (2003) might be interpreted as evidence of tactical behavior organized to evade interference by adjusting risky ventures to changes in human orientation, proximity, and attention. In their study, dogs were exposed to training in which a piece of food was placed on the floor, whereupon the experimenter looked at the dog and said "Aus!" (Out!), followed by a second event in which the dog's name was called and followed by "Aus!" again. The dogs were subsequently exposed to a series of test trials that continued until the dog either took the food or 3 minutes had elapsed. If the dog took the food without permission, it was not punished, nor was it rewarded if it refrained from taking the food. As such, the procedure appears to asymmetrically favor approach over avoidance, since dogs that took the forbidden food were merely ignored, just as those that obeyed the prohibition were ignored. With only one exception, all of the dogs took the food at least once, and some of them took food on several occasions while they were watched. However, watched dogs generally avoided the forbidden food but readily took the food if released to do so or when left alone with it. In a follow-up experiment, the dogs appeared to be aware of the attentional state of the experimenter based on the orientation of the experimenter's direction of gaze. When the experimenter faced the dog with closed eyes, the dog tended to respond to the frontal orientation as it did when the experimenter's back was turned to the dog. These findings suggest the possibility that dogs might know when they are being carefully observed. When closely watched, the dogs broke the prohibi-

tion against taking the food much less frequently, engaged in more indirect approaches to the forbidden item, and appeared less relaxed (i.e., sat more often and laid down less often) during the test trial. The indirect approach might have enabled the dogs to keep an eye on the experimenter while nearing the object or taking a more advantageous position from where to approach the food item.

A remarkable aspect of the experiment by Call and colleagues is the degree of appetitive suppression achieved by virtue of two vocal warnings, essentially events that emphatically served to draw the dogs attention to the food in association with a social startle/threat implication. One possible explanation for the extraordinary control exerted by vocal reprimands may stem from the unfamiliarity of the testing situation and the person delivering the threat. Another possible factor might be traced to prior inhibitory training. Some of the dogs may have received aversive inhibitory training that conditioned them to refuse food not given to them by the owner (e.g., poison proofing). Poison-proofed dogs usually show a strong avoidance and rejection of illicit food that they might find or have offered to them by strangers. In contrast, the dogs in the test group eventually took food when released or when left alone, strongly suggesting that they were not behaving under the influence of situational anxiety or aversive inhibition. Apparently, the experimenter remained neutral whether a dog ate the food or not. From a behavioral aspect, the effect of such a procedure would be far from neutral. In fact, such a strategy should have resulted in a significant differentiating effect with respect to dogs that ate and those that were inhibited. Dogs that ate the food in the presence of the neutral experimenter should have been doubly gratified by the disconfirmation of the avoidance contingency and by the successful control established over the food item without cost or interference. Learning theory predicts that such rewarding outcomes should reduce inhibition and conflict in dogs about taking food in comparison to dogs that continued to avoid the food.

Appetitive Suppression, Social Attraction, and the Attribution of Intention

Matters are further complicated by the fact that dogs tend to cope with social inhibitory conditioning in ways that are highly variable and strongly influenced by constitutional differences and prior rearing practices (Freedman, 1958). Freedman studied the ontogeny of these effects in several breeds. Puppies selected from these breeds were divided into two groups: one group had been reared with disciplinary handling and the other reared with social indulgence. At week 8, disciplined and indulged puppies received several days of inhibitory training during which they received swats on their rumps together with loud vocal reprimands whenever they ate meat from a bowl that was located in the middle of a room. The aversive contingency exerted a differentiating effect on social and appetitive approach behavior that was correlated strongly with the rearing breed of the puppy and only partially with rearing history.

After the experimenter left the room, basenjis, which showed a strong environmental and novelty orientation, tended to eat from the bowl straightaway, whether they had been punished or indulged, whereas shelties, which showed a strong social avoidance, consistently avoided the food during the full 8 days of testing, regardless of their rearing history. In contrast to the social aloofness of the basenjis and the social avoidance of the shelties, the beagles and wirehaired fox terriers showed a high level of attraction and interest in the experimenter. Depending on their previous rearing history, these breeds also differentiated into separate groups after punishment training. Indulged puppies showed a greater amount of avoidance toward the meat than did puppies that received disciplinary treatment prior to punishment. Of particular interest with respect to the long-term effects of such treatment, indulged beagle puppies receiving punishment training at week 8 showed evidence of delayed changes in social behavior consistent with a loss of trust and safety stemming from the earlier punitive experience. During follow-up tests from weeks 11 to 15, these indulged-punished beagle puppies became wary when approached by

handlers and increasingly difficult to catch—behavior that sharply contrasted with their earlier sociable attitude and behavior. The so-called second fear period may actually be related to the retraction of residual social attraction or its loss as the result of interactive conflict, releasing conditioned social fear acquired earlier in life.

Freedman's findings indicate that early rearing practices and individual differences can strongly influence how dogs respond to appetitive inhibitory training. The individual differences associated with appetitive inhibitions would seem to represent a significant confounding influence for cognitive studies such as the one performed by Call and colleagues. According to Freedman's work, some dogs should simply avoid food in the presence of the experimenter, whereas others should simply ignore the warning and take the food at the first opportunity. Dogs most likely to differentiate behavior in response to reprimands would need to have a high level of social attraction.

Another problematic influence is prior safe or unsafe exposure to food. Under normal household conditions, dogs frequently find bits of food fallen to the floor, which they are usually permitted to eat without consequence. Most dogs are also accustomed to obtaining food as rewards from their owners or to obtaining it by searching countertops and trash bins—efforts that are intermittently successful and may persist despite the use of contingent and belated punitive efforts. Dogs regularly receive small portions of food as rewards consequent to the performance of obedience tasks. Food is also sometimes used to relax anxious dogs via its calming effects on aversive emotion and arousal. The idea here is that preexposure to food would likely build a significant level of prior conditioning and bias that should impede or facilitate the acquisition of inhibitory conditioning (see *Stimulus Factors Affecting Conditioned-stimulus Acquisition and Maintenance* in Volume 1, Chapter 6). Further, there might be an intrinsic contrapreparedness associated with learning to avoid appetitive objects via aversive threats. Rats, for example, exposed to brief foot shock and other aversives (e.g., ammonia, mustard, or quinine) as they approached a highly preferred food item (an Oreo cookie), or as they ate the cookie, continued to show a persistent appetite for the object. In contrast, rats exposed to nausea-producing lithium chloride acquired a rapid and cross-contextual aversion toward the cookie, perhaps indicating a certain degree of independence between cutaneous and alimentary defense systems. When subsequently tested, the shocked rats showed only momentary hesitation before eating the cookie in the training cage where the shock took place but showed no hesitation before eating the cookie while in the home cage or when tested in a novel cage (see *Prepared Connections: Taste Aversion* in Volume 1, Chapter 5).

Despite biological contrapreparedness, lasting food inhibitions can be established rapidly with severe physical or electrical punishment but not without risking neurotogenic elaborations. Lichtenstein (1950) demonstrated that appetitive behavior could be fully suppressed by the delivery of one to three electrical shocks (2 seconds of 85-volt AC each), if the aversive events were timed to overlap the act of eating, whereas significantly more repetitions of shock stimulation (23 to 29 shocks) were required if it was delivered immediately before the presentation of food (see *Lichtenstein's Experiments* in Volume 1, Chapter 9), again raising additional questions about the size, durability, and ease with which Call and colleagues were able to establish a stable inhibition of appetitive behavior.

Chairs and Minds: On Knowing What a Dog Knows About Attentional States

A more serious set of problems for Call's attentional state hypothesis is posed by the findings reported by Solomon and colleagues (1968). The experimenters were interested in the delay of punishment effects on the highly motivated appetitive behavior of starving dogs. During the training phase of the experiment, the dogs were deprived of normal rations and caused to lose more than 20% of their normal body weight. They were presented with two food bowls, one containing 20 grams (approximately a tablespoon and a

half) of dry food and the other containing 200 grams (less than a cup) of horse meat. The food bowls were arranged so that they were within the reach of the experimenter, who sat in a nearby chair armed with a tightly rolled-up newspaper in hand. If the dogs limited their interest to the dry food, which they were permitted to eat, they were ignored without consequence; if the dogs ate the meat, however, they were hit sharply across the nose with the newspaper. Some of the dogs were swatted just before they touched the forbidden food, whereas others were punished after a 5- or 15-second (s) delay, during which they were allowed to eat. Dogs showed a spectrum of intense fearful behaviors and sustained food aversion differentiated in various ways depending on the timing of punishment. Approach toward the forbidden food item was suppressed rapidly in all three groups of dogs, requiring as few as three or four hard swats.

After the training phase, the dogs were given several daily 1-hour feedings to allow them to regain the weight they had lost. At the end of this period, the dogs were deprived of all food for 2 days. During the testing phase, all food was obtained during "temptation tests," which consisted of dry kibble and a bowl of horse meat. The experimenters found that dogs were so intimidated by the treatment that they would starve themselves, on average, for 16.3 days (no delay), 9.7 days (5-s delay), and 1.5 days (15-s delay) rather than eat the preferred meat, even though the experimenter was out of the room and the punishment contingency had been discontinued.

An interesting aspect of this disturbing study is the finding that the dogs showed opposite patterns of social behavior, depending on whether punishment was immediate or delayed. The no-delay group, upon entering the experimental room, skulked around with the head and tail down and staying as far away from the experimenter and the forbidden food as possible. In contrast, the delay groups entered the experimental room with an appearance of immense excitement, tail wagging, and jumping up on the experimenter. As they approached the food and took a few bites, their behavior dramatically changed: with their tail drooping down, they would slink behind the experimenter's chair or circle the room, go to a wall, and then crawl on their belly to the experimenter, whereupon they would wag their tail, furtively take some more food, and retreat again. During the test phase, when the dogs were left alone they behaved as though the experimenter was still present. Even though they were free to eat the meat, they could not initially do so. In the case of no-delay dogs, the taboo broke down very slowly, but when they finally began to eat the meat they did so in an uninhibited fashion, wagging their tail and not showing any sign of anxiety. In contrast, when the delay dogs finished eating the dry food, they would often put their paws on the experimenter's chair or go behind it from where they would wag their tail when they looked in the direction of the empty chair. The dogs appeared to treat the chair in ways that mirrored the behavior they showed when the experimenter was in the room. For these dogs, the taboo against eating the meat broke down much more rapidly, but they never lost their apprehensiveness while eating and remained anxious after eating.

The findings reported by Solomon and colleagues are at significant odds with the attentional state hypothesis. The 18 dogs in this experiment appeared unable to differentiate the relative degree of threat posed by the presence or absence of the experimenter. In fact, in the case of those dogs punished after a brief delay, they continued to treat the experimenter with animated excitement at the beginning of each session, only showing evidence of fear after they had taken some food. The trigger stimulus of anxious arousal relative to the experimenter was elicited by the act of taking food, not by the presence of the experimenter. During the test phase, the delay dogs were observed to approach the chair and behave as though the experimenter was still present. Of course, a chair does not possess an attentional state, but the dogs nevertheless showed behavior toward the chair and surroundings as though it did. The authors interpreted this social behavior in vacuum as an expression of *conscience*.

Whether the previously described experiment performed by Solomon and colleagues would qualify as such falsification is not clear, but it does raise a number of questions about how dogs perceive and use human attentional states. The questions raised here need to be answered by means of clever experimental designs that can unambiguously rule out lower levels of organization (e.g., stimulus and context learning). The accumulated data of 100 studies performed to prove some inductive belief or generality are vulnerable to upset based on a single well-designed experiment demonstrating an irrefutable counterexample. The use of vocal threats or physical punishment to test cognitive capacities seems particularly onerous, clumsy, and inappropriate to the task, especially insofar they are likely to impact a dog on numerous levels, making it difficult to disambiguate a canine orientation to attentional states and a complex chain of conditioned responses associated with the object and surroundings.

A problematic aspect of Solomon and colleagues' method deserves mention, to wit: how was the experimenter able to swat dogs belonging to the 15-s-delay group while they were still eating. Considering that these dogs were starved, one would expect that several of them (at least) should have been able to bolt down 200 grams of meat in less than 15 s and thereby beat the punishment contingency. Frankly, the notion that a starving dog would take 15 s to eat less than a cup of meat seems inconceivable.

Complex Social Behavior and Model/Rival Learning

Dogs appear to be highly sensitive to social modeling and training effects that occur in the context of exchanges between two human demonstrators—a trainer and a model/rival—interacting with an attractive object in the dog's presence. The method of model/rival (M/R) training has been most thoroughly investigated in the context of training parrots (see Todt, 1975; Pepperberg et al., 1999; Pepperberg, 2002). Todt's work with parrots is organized around the incentive value of attention directed toward a familiar and previously cooperative person who has ceased to be so and made to become a *rival* for the attention of a second person who remains a cooperative *partner* to the bird. In this paradigm of instruction, the rival's vocal expressions prompt close attention and interest by the partner (trainer), thereby modeling vocal behavior relevant to attracting attention and interest from the cooperative partner. Whether the incentive governing the acquisition of vocal behavior is related to reward associated with social attention or merely the result of focusing the bird's attention on the rival's behavior is unclear, but Todt notes that, while the birds learned words from the rival, they tended to use words to communicate with partner/trainer.

A study by McKinley and Young (2003) purports to compare the relative efficacy of a modified M/R method with shaping for training a vocally discriminated selection-and-retrieval task. The authors suggest that both methods perform about equally well. However, since the design is not adequately controlled for making comparative assessments (e.g., all of the dogs had been previously trained to retrieve), it is difficult to say what the study results actually measure. From the brevity of the training used to reach criteria levels and the weight of other evidence provided, the comparable performance of the dogs tested was probably the result of transient motivational changes, classical conditioning, and prior training to retrieve, rather than reflecting effects specifically due to instrumental or M/R training. Another possibility is that the results reflect a prepared ability to rapidly associate word meanings with the act of retrieving objects via a process akin to *fast mapping* (Kaminski et al., 2004). At a minimum, such experiments require that baseline data be obtained to assess prior learning and skills that might confound the behavioral change that one wishes to use as a comparison to measure the relative effects of the independent variables. Since such baseline data were not collected, it is impossible to determine from their data whether any significant effect on retrieve behavior occurred as the result of either of the training procedures. Further, the experimenters moved immedi-

ately from the training procedure to the test trial, suggesting that the comparable effects of the two methods may have been due to arousal and motivational changes (establishing operations) activated by the target object that in turn served to recruit previously learned retrieval responses.

Preliminary Experiments and Observations

Preliminary results of a series of experiments performed to explore possible effects of a modified M/R method indicate that dogs may be more sensitive and responsive to social learning via observation than previously suspected. These experiments appear to reveal a form of rapid complex social learning in dogs that was not previously described in the scientific literature. The experiments indicate that dogs may rapidly acquire and integrate the attunement dynamics of two persons making exchanges involving an object valued by the dogs.

The procedure consists of an observing dog, a partner/trainer (P/T), a model/rival (M/R), and an object of significant interest (OSI) to the dog. The M/R plays a combined role of stimulating rivalry for the trainer's attention while attuning and modeling behavior in response to the P/T's signals, prompts, and rewards. The experiments were performed in a home environment and involved two familiar demonstrators, who sat on the floor facing each other approximately 3 feet apart. The dog, a 2-year-old, male, Belgian Malinois, was signaled by the P/T to lie down and to stay at approximately 6 feet away from the P/T and the M/R. The dog showed a strong interest in both objects used in experiments 1 and 2.

Experiment 1

The first experiment (1A) involved the dog observing the demonstrators interacting with a favorite toy (a ball). In the first interaction, a brief fuss was made over the ball while the demonstrators tugged back and forth on it. The P/T finally pulled the ball forcefully away from the M/R, and then, after a brief pause, the ball was put on the floor approximately 2 feet away from an identical ball. The dog was released and observed. A second experiment (1B), employing an identical arrangement, was performed immediately after experiment 1A. This time, though, the demonstrators interacted more quietly and cooperatively, with the P/T now giving the M/R the ball with "Take it," saying "Good," and then asking the M/R to give the ball back with "Out." As the M/R handed the ball back, the P/T said "Good" and immediately thereafter gave the object back again in a friendly way, saying "Take it" and "Good" as the M/R took the ball again. This pattern was repeated two or three times before the ball was placed on the floor in the manner previously described.

The results of these experiments were extremely surprising. Observing human interaction with the ball beforehand exerted a pronounced affect on the dog's subsequent response to the object. In the case of experiment 1A, the dog went directly to the ball, rapidly picked it up, became unusually possessive over it, and made vigorous efforts to evade being caught when the P/T tried to take the ball. This behavior was in striking contrast to the dog's ordinary willingness to give and release toys. Equally striking and remarkable was the dog's change and demeanor following experiment 1B. After observing the demonstrators interact in a more friendly and cooperative way with the item, the dog went to the ball, picked it up in a much more relaxed manner, went to the P/T, and allowed him to take it away. Extraordinarily, these dramatic changes in complex social behavior were produced within the context of a 10-minute period.

Experiment 2

Several days later, the same dog was observed under a similar basic arrangement, but this time another toy (e.g., a stuffed animal) was used and the P/T and M/R staged another set of exchanges for the dog to observe. In the first of these experiments (2A), the P/T showed the object to the M/R, sharply said "Leave it," and made a slapping action toward

the M/R's hand. This procedure was repeated two or three times. After a brief delay, the toy was put on the floor and the dog released. In the second experiment (2B), the P/T presented the toy to the P/T, saying "Take it," and then "Good" as the M/R took the object. After a moment, the P/T, saying "Give," asked nicely for the object, whereupon the M/R handed the toy back and P/T said "Good." This friendly exchange was repeated two or three times, before the object is placed on the floor and the dog released.

Again, quite unexpectedly and surprisingly, the dog's behavior toward the toy changed rapidly in directions consistent with the way in which the P/T and M/R interacted with the object beforehand. In the case of experiment 2A, the dog, normally highly object driven and enthusiastic, only slowly and tentatively approached the object, then hesitated, and turned away without picking it up. Instead of taking the object, the dog went to the M/R, as though to check on her, while appearing to ignore and avoid the P/T. By contrast, after observing the cooperative interaction between the P/T and the M/R staged in experiment 2B, the dog went directly to the toy, picked it up, and took it to the P/T.

Social Cognition, Scripts, and Modal Styles

The clarity, contextual appropriateness, and rapidity of the complex behavioral adjustments shown by the dog in response to observing social exchanges between the P/T and M/R were truly extraordinary, going well beyond what one might expect from the low estimations normally attributed to observational learning in dogs (see *Social Learning* in Volume 1, Chapter 7). The dog seemed to grasp accurately the social significance of the interaction between the P/T and the M/R and to adjust its behavior immediately toward the object and the demonstrators accordingly, as though he had directly experienced the stimulation firsthand. These remarkable changes in behavior, occurring in response to staged demonstrations, suggest that the model/rival procedure may offer a powerful tool for studying developmental processes, affect-attunement dynamics, and canine proxemics (see *Model/Rival Theory, Fair Play, and Sibling Hierarchy* in Chapter 8), as well as suggest a variety of behavior therapy and training applications. For example, in addition to an apparent value for developing object preferences and avoidance, dogs exhibiting possessive or overt guarding behavior might be helped to interact in a more friendly and cooperative manner by observing a trainer and model/rival exchanging positive vocal signals and gestures signifying safety and comfort around trigger objects. In addition, it may have value in the context of reducing impulse-control deficiencies by demonstrating to the dog more calm and cooperative exchanges organized around desirable objects. The apparent attunement and social scripting fostered by M/R method may help to explain certain social excesses associated with hyperactivity. For example, in situations where children routinely roughhouse around objects of interest to a dog, M/R learning effects may strongly affect the dog's behavior toward the children and the objects.

The robust and remarkable effects produced by the M/R method is deserving of experimental scrutiny. The apparent sensitivity that dogs exhibit for attunement information derived from social demonstration suggests that such learning may play a significant role in behavioral organization. The arrangement does not exclude the possibility that the dog might be responding to conditioned or unconditioned stimuli that generate preparatory arousal and subsequent expressive behavior similar to the rival's modeled behavior. Of course, such preparatory influences would not necessarily be incompatible with the possibility that such interaction might also exert cognitive organizing effects. Further, even if the effects are restricted to the transmission of attunement effects, such capacities for behavior-therapy purposes are not insignificant. The dramatic and rather precise nature of the behavioral output associated with M/R demonstrations is consistent with the possibility that M/R learning might involve processes that conduce attunement and encode modal scripts or styles of exchange with the object mirroring the model/rival's behavior. This

hypothesis is consistent with the tendency of some young dogs to adopt various modal styles and nuances of behavior shown by other dogs perceived as possessing effective leadership qualities (perceived high power). Model/rival learning appears to enable observing dogs to mirror the affect and actions observed between the M/R and the P/T. Structuring behavior in accord with attunement scripts observed taking place between the M/R and P/T would allow dogs to integrate rapidly into social activities. Such abilities might be particularly active in the modal behavior and styles of playful newcomers and young animals seeking acceptance into an established social group. The capacity to exhibit behavior that "feels" like the style of others may cause group members to perceive the newcomer as being familiar and to more readily accept and integrate the *poser* into the group.

Attention, Model/Rival Learning, and Mirror Neurons

The ability of dogs to *style* behavior in conformity with the attunement dynamics observed between demonstrators would suggest the involvement of a complex computational apparatus for extracting socially significant information and making accurate affective inferences about its significance. One line of neurobiological research in monkeys has shown that the ventral premotor cortex encodes a mirror representation of the actions made by others of a form similar to the representation made when the animal makes the action itself (Umilta et al., 2001; Ferrari et al., 2003). In addition to actions seen, these mirror neurons represent what is heard in association with actions but remain inactive to other sounds (Kohler et al., 2002). Mirror neurons appear to provide the animal the ability to discriminate action based on auditory, visual, and motor information (Keysers et al., 2003). These findings suggest the possibility that these mirror neurons may be part of a larger network comprising a neural matching/comparator system that would enable social animals to rehearse the form or script of social behavior observed in the behavior of others before acting on it. Thus, the encoding of a mirror representation at the stage of premotor processing may be "transformed into potential actions in the mirror system such that the perception-action link related to action representation is activated already during observation" (Nishitani and Hari, 2000:918). The ability of parrots to acquire and express complex vocal sounds based on hearing in the context of model/rival enactments may be facilitated by a similar process of mirror representation whereby complex vocal sounds are encoded by auditory mirror neurons and subsequently decoded by motor programs controlling vocal behavior.

The observed action represented as potential action by mirror neurons may be attributed with affective significance by cortical and limbic processing before being expressed as an action attuned to the social circumstance. Unlike parrots with their imitative behavior, dogs may be more inclined to recast the potential action represented by mirror neurons by turning attention toward the quality of feeling informing the observed exchange. According to this hypothesis, dogs are more interested in the affective significance of the M/R demonstrations than in imitating the specific form. These sorts of prepared social learning capacities may be particularly important to domestic dogs, whose social acceptance depends on their ability to attune and commune with family members. The genetically augmented play capacities of dogs may include an automatic representational framework for decoding and attributing affective significance to potential actions, enabling dogs to transition from the external form of playful exchanges to a subjective experience of shared internal feelings (joy) arising in the process of mediating attunement and secure attachments.

PART 3: ETHICS AND PHILOSOPHY

Cynopraxis and Ethics

A Delta Society publication aspiring to set professional standards for dog trainers lists three primary ethical criteria that the authors believe qualify a procedure as humane:

"Humane dog trainers use and advocate methods that rely on: eliciting and reinforcing desired behaviors, inhibiting and discouraging unwanted or potentially dangerous behaviors, minimizing the use of aversives while doing either of the above" (Delta Society, 2001:2). Defining ethical behavior exclusively in terms of technical means irrespective of aims is inherently circular and limited with respect to ethical practices.

Ends

Without defining the aims of training, such rather tinny behavioristic criteria as set by the Delta Society are virtually meaningless with respect to humane-practice criteria. Numerous questionable training activities might be construed as ethical and humane practices merely because they are performed in adherence to these sorts of standards. The second criterion violates the dead-dog rule and the third criterion neglects to consider the adverse impact of overly intrusive methods (see *Hydran-Protean Side Effects, the Dead-dog Rule, and the LIMA Principle*). According to these recommendations, putting a dog in a crate and training by means of a tedious autoshaping program would be considered ethical and humane, even though a human is never involved in the training process. Evaluating the ethical and humane use of means in the absence of appropriate consideration of the ends to which they are applied is logically flawed and produces many absurd implications. For example, dogs trained by the Russians during World War II were desensitized and conditioned with food rewards until they either ran between the treads of an approaching tank or ran alongside it, whereupon an ordinance strapped to their bodies was detonated. Since antitank dogs were trained by "eliciting and reinforcing desired behaviors," applying the aforementioned criteria suggest that training of antitank dogs was ethical and humane.

The criteria listed for identifying behaviors to be reinforced or "inhibited" are strictly limited to anthropic interests; that is, those canine activities that the trainer finds desirable or undesirable without reference to the dog's needs and QOL. Canine adjustment problems cannot be effectively treated without normalizing the social and environmental circumstances producing the objectionable behavior. Merely reinforcing or punishing what one likes and dislikes is not likely to prove very beneficial in the long run.

These concerns emphasize the profound influence that training objectives have on matters pertaining to ethical standards. A ruthless person may use kindness and gifts in order to deceive and gain the confidence of others, with the goal of eventually harming or taking advantage of them in some way. Such manipulation is obviously unethical and can hardly be considered humane. In a poignant way, Bertrand Russell (1997) has stressed the potential risks associated with the formation of faulty expectations based on an assumed uniformity between means and ends:

> Domestic animals expect food when they see the person who feeds them. We know that all these rather crude expectations of uniformity are liable to be misleading. The man who has fed the chicken every day throughout its life at last wrings its neck instead, showing that more refined views as to the uniformity of nature would have been useful to the chicken. (63)

Russell's chicken, like the Russian antitank dogs, was duped by a faulty extrapolation from means to ends.

Under natural conditions, animals change their behavior in order to improve their ability to control environmental resources and events that contribute to their survival and well-being. Accordingly, instrumental behavior is strengthened when it succeeds in enhancing an animal's ability to predict and control the occurrence of some significant event and weakened when it fails. Dog training is based on a contrivance that exploits canine learning to shape and control an artificial repertoire of behaviors patterned toward some training objective that may or may not be in a dog's best interest. In the context of training, reward and punishment are arbitrarily arranged to occur in accord with the trainer's plans to render the dog's behavior more predictable and controllable. The dog's ability to predict and control these events is preempted by rules established by the trainer in advance; that is, the game is rigged to allow

only those changes in the dog's behavior that suit the trainer's purposes.

Just as a dog's behavior is shaped by its ability to control attractive and aversive events arranged by a trainer, the trainer's behavior is subject to modification by the relative success or failure of training exchanges to meet objectives. Efforts that successfully increase control over a dog's behavior are strengthened, whereas efforts that fail to increase control are weakened. As such, practical dog training is inherently reward based insofar as contingencies are arranged to enable dogs to gain control over motivational events by means of signaled actions consistent with the training objective. Only an irrational trainer would set up contingencies that were deliberately arranged to make a dog fail. The most unethical and punishment-based training does not stem from the use or nonuse of aversive motivational stimuli but rather from incompetence. Incompetent trainers may lack the basic know-how and skill to use basic procedures humanely or to organize the contingencies and steps of a training plan. As a result of an inconsistent or incoherent organization of training events, dogs may be unable to control significant attractive and aversive motivational stimuli, thus resulting in persistent punishment, distress, and an adverse overall impact on their ability to cope.

Competent dog training is intrinsically rewarding and bond enhancing, whereas incompetent training is intrinsically punishing and bond degrading. The enhanced control resulting from successful training yields an enhanced capacity for the partnership to produce mutually rewarding exchanges that enable the partners to enjoy each other while adjusting and learning about each other. Conversely, social exchanges that result in a loss of mutual control tend to promote increased punitive interaction and conflict. The interactive conflict stemming from incompetent exchanges contributes to an increased reliance on excessive confinement and isolation, emphasis on passive head and jaw restraint, and needless distress.

The practical ends of dog training have significant welfare implications, especially for dogs trained to perform services that are inherently aversive and require significant compulsion to achieve. One cannot disclose the nature of one's training objectives to a dog in advance, nor can it appreciate intuitively the significance of its training. To some extent, the dog's innocence and ignorance with respect to the end task renders the ethical dilemma somewhat less consequential than if the dog was deliberately kept in the dark by deception and omission regarding ultimate aims and purposes. However, to the extent that the dog is an object of care, its innocence about such matters obligates the trainer, as a *humane* being, to consider thoughtfully the ethical implications of training procedures and the practical purposes for which the dog is trained. Training goals that are ultimately enslaving or harmful to a dog are inherently unethical and cruel, regardless of the means used to attain them.

One hypothetical test that can serve as a general guideline for making decisions about practical use is to ask oneself whether the dog, given a choice, would likely select the career being chosen for it. The notion that a dog might truly love to work is not far-fetched, since selective breeding has produced a staggering array of canine skills integrated with ready-made motivational systems that make their performance intrinsically rewarding. Breeding biologically prepares dogs with drives and functional capacities that are uniquely compatible with certain practical tasks while being inimical to others. Dogs are born with a set of innate threshold values predisposing them toward certain traits and action modes. These predispositions point toward activities that a dog seeks and is gratified to perform. These various preferred activities represent a core focus of competency that a dog is naturally inclined to integrate skills around. Discovering a dog's core competency and building on those interests and incentives is an important aspect of both cynopraxic and practical dog training. Integrating skills relevant to a dog's core competency serves to activate power and freedom incentives, which are typically expressed in playful activities of various kinds. The availability of these playful activities can be budgeted and made to overlap with the performance of related practical

activities of significant value to the trainer but of no particular significance to the dog, except insofar as resonating with core interests and affording an opportunity to play or the possibility to obtain other rewards. When training working dogs, the competent trainer discovers, stimulates, refines, and sublimates various innate appetites and propensities (drives) conducive to the performance of useful services in accordance with the accepted cultural and functional expectations of the breed.

Just as a competent craftsperson would not use a screwdriver in place of chisel or a wood saw to cut metal pipe, a competent trainer would not train a beagle to hunt grouse or train a Brittany spaniel to hunt rabbit. In essence, the practical trainer's work is to actualize an innate potential present in the dog for some useful activity. As a result of such training, a convergence human and canine interests dovetails, with the dog obtaining significant gratification and playful stimulation as the result of performing some valuable practical activity, thereby satisfying both the trainer's objectives and the dog's interest in play and companionship. Dogs successful in such work have an increased likelihood of being bred and thereby perpetuating the genes responsible for their responsiveness to training.

The foregoing represents the ideal circumstances surrounding the training of working dogs, whether they are used for military scouting and reconnaissance, drug and explosive detection, search and rescue, hunting, herding, and so forth—dogs work to play. Some training objectives, however, require that dogs perform work for which they are neither biologically prepared nor from which they can obtain play gratification. Training dogs for such purposes requires the implementation of means other than play to shape and render reliable the requisite repertoire of trained behavior needed to perform the service. Typically, such dogs are systematically manipulated by social encouragement together with the presentation and withdrawal of attractive and aversive motivational stimuli in the process of compelling adjustments compatible with the training objective that they would otherwise not perform. These issues raise difficult ethical questions, requiring that one weigh the cost of such training and service to the dog versus the potential social benefits that the service provides for the end client. If the social value of the service is minimal or harmful to society, it is easy to conclude that such training is inappropriate. It is sobering, though, to consider the previously mentioned Russian antitank dogs in the context of a social cost-benefit assessment. From the perspective of the Russian military and a great many Russian people faced with a mortal threat, such an end use of dogs was probably considered a tremendous social good. Indeed, the use of such dogs may have saved Russian lives, but the notion of training dogs to become living bombs is abhorrent, just as making prostitutes of adolescent children for the sake of espionage is abhorrent. In both instances, the violations of innocence and trust make such uses intrinsically inhumane. This example underscores the danger of ethical judgments weighted in the direction of social cost-benefit assessments and social consensus without appropriate consideration having been given to the cost and harm to the dog.

The line becomes even more blurred in the case of some canine services that provide a significant amount of social benefit, such as those performed by assistance and guide dogs, but involve the training of unprepared action sequences. As noted previously, in addition to reward-based training efforts, such practical training activities often require a significant amount of inhibitory training and compulsion. Unlike working dogs in which the end use is compatible with breed-typical appetites and drives, some service applications are intrinsically foreign to dogs (see Serpell et al., 2000). Dogs that perform such services do so as the result of intensive training that gradually shapes a repertoire of behaviors having little intrinsic reward value for the dogs themselves but possessing immense comfort and reward value for persons needing such assistance. Although the close interaction and companionship provided by the client-caregiver provide the dog some compensation, nevertheless such dogs would also benefit

from special compensatory stimulation consistent with their breed-typical play and work interests when not performing services, including appropriate opportunities to play and exercise—activities that the client-caregiver may not always be able to provide the dog. Perhaps what is needed is a national volunteer-type organization that would provide *assistance* to these dogs and their owners in the form of play and other outdoor activities not otherwise available to them.

There is nothing intrinsically incompatible between cynopraxic priorities and work, provided that the training process is competent and consists of bond-enhancing exchanges that improve a dog's QOL. These cynopraxic priorities stress that the working dog *team* is the result of a mutual process of adaptation conducive to belongingness, playfulness, and trust. Even relatively unnatural skills, if trained in a competent manner and gradually brought under the motivational influence of power and freedom incentives, can become the source of significant pleasure for a dog to perform.

Although practical dog training can involve behavioral objectives that are exploitive or inimical to a dog's well-being, many practical uses of dogs can be achieved in a manner that does not run afoul of cynopraxic bond and life-experience imperatives. Some authors have argued that working dogs, in principle, cannot be effective workers while living in a home as companions, suggesting that selective breeding for traits that make them good working dogs bars them from making good household companions. These sorts of general hypotheses conflict with numerous counterexamples indicating that working dogs can, and do, enjoy the QOL benefits of companionship and still remain effective workers (see Kiley-Worthington, 1990). Finck (1993), who studied the affect attunement between children and dogs, found that working and hunting dogs were generally highly receptive to a child's attunement efforts, which is consistent with the enhanced abilities of such dogs to follow human instruction.

Breeding that would so alter behavioral thresholds in ways that preemptively excluded a dog from household companionship would likely also significantly impair the dog's capacity to perform most types of cooperative work. The notion that canine traits conducive to work are incompatible with domestic life is unfounded and contradicted by common experience, since thousands of police dogs have demonstrated that they can be both good workers and welcome household companions. Many police departments in the United States use dogs that work and then go home with the officer/handler as companions. Police dogs share the risk of a dangerous job and are entrusted to make safe contact with the general public. Why, then, should they be denied the familiar surroundings of the home after their duty shift is over? How might the isolation and confinement of overnight and weekend stays in a kennel help such dogs in their work? Dogs are first and foremost companions who are also helpers, and specialized uses of canine labor that preemptively exclude them from living in a home or deny them the benefits of human companionship so that they can be made into cheap and useful "tools" raise a number of significant welfare concerns.

Means

The purposes and ultimate goals of training obviously affect the ethical assessment of the means. With the broader picture of ends in place, a more sensible discussion of means is possible. First and foremost, procedural means are employed to produce some series of immediate effects toward the realization of an ultimate goal or objective. In dog training, these means consist of a variety of manipulations involving the differential application and removal of attractive and aversive stimuli with the intent of altering a dog's behavior in some way. The ethical implications of means depend on a number of competing considerations. There is a widely held belief that attractive stimuli are of a more humane and ethical nature than aversive ones. Of course, both people and dogs share a preference for pleasure over pain; however, the ultimate significance of attractive and aversive stimuli depends not only on their momentary hedonic and emo-

tional effects but also to a significant extent on ultimate ends and the aggregate effects that such events have on the human-dog relationship and the dog's QOL. The experience of brief discomfort in exchange for the acquisition of long-term safety from pain or injury, together with increased opportunities for pleasure and liberty, unquestionably warrants the limited use of such stimulation, especially if other means are not available for producing a similar effect in a timely manner. However, using only mildly aversive or annoying procedures might be considered inhumane in situations where nothing of lasting benefit is achieved.

Motivational stimuli consist of hedonic (likes and dislikes) and incentive (needs) values. Seeking pleasure, comfort, and safety, on the one hand, and avoiding pain, loss, and risk, on the other, are strong motivational incentives regulating both human and dog behavior. Such events also exert influential excitatory (arousal) and inhibitory (calming) autonomic effects. Training consists of the response-contingent application of both attractive and aversive events in order to change a dog's behavior in some specific or general way. Applying aversive stimulation excessively, incompetently, or unnecessarily represents prima facie abusive treatment. Although the arbitrary and incompetent use of attractive and pleasurable events does not invite similar criticism, it too can be highly abusive and destructive. Since attractive incentives can be used to deceive or to obtain ends harmful to a dog or fail to obtain beneficial ends, a reliance on nonaversive procedures may be unethical in cases where the training objectives are contrary to the dog's best interests or when they result in harm to the dog that could have been averted by the use of a more effective but aversive procedure. Conversely, aversive procedures that cause significant discomfort but act as a means to some beneficial end (e.g., prevent the dog from running into the street) may confer a positive moral value to the procedure insofar as it is efficacious and achieves, on the whole, an ultimate good that could not have been achieved by nonaversive efforts alone.

When considered independently of ends, attractive events and aversive events are morally indeterminate, although the former is hedonically preferable to the latter. Consequently, on balance, if some behavioral objective is equally obtainable by attractive or aversive means, then the trainer, with due respect for the dog's preference for pleasure, is ethically bound to use attractive means rather than aversive ones. On the other hand, if some behavioral objective promising benefit to the dog is obtainable only by aversive means, then the trainer, with due consideration for the dog's well-being, is ethically obligated to use the least aversive procedure necessary. However, on the whole, the competence and confidence needed to integrate an adaptive coping style depend on a balance of reward derived from the successful control of both attractive and aversive motivational stimuli. To conceive of attractive stimuli as being intrinsically good and beneficial to a dog's welfare and aversive stimuli as being intrinsically bad and inimical to a dog's welfare is the brew of fanatics, not the fruit of science or a sincere concern for the dog's welfare. From the perspective of cynopraxic theory, punishment, especially those efforts that thwart or attempt to suppress a dog's control efforts by incompetent interference or excessive confinement or restraint, is a far more significant and serious threat to canine welfare than is the balanced use of aversive motivational stimuli in the context of reward-based training.

In practice, the decisions regarding the use of valenced motivational stimuli involve a variety of practical and ethical considerations. At minimum, for attractive and aversive events to be used humanely, the trainer must possess sufficient skill to apply them effectively for the purpose of attaining well-defined target objectives (competency factor) and possess a reasonable idea of the immediate and remote consequences of the events used, including a realistic appreciation of potential side effects. In addition to general training and behavioral knowledge, the trainer must also possess significant experience with dogs of different breeds and temperament types at various ages—factors that strongly

influence the selection and appropriateness of training procedures.

OWNER CONTROL STYLES AND WELFARE AGENDAS

Hiby and colleagues (2004) have collected and analyzed questionnaire data ostensively relevant to owner control and disciplinary styles, however, the interpretation and conclusions they present of their findings appears to belie a negative bias and agenda against the use of aversive motivational stimuli in dog training. Among these findings, they found that dogs receiving high obedience ratings from their owners were rewarded more often than counterparts receiving low obedience ratings. This finding suggests a rather obvious and straightforward implication: owners are more likely to reward obedient behavior than they are to reward disobedient behavior. That low obedience ratings were associated with a higher frequency of punishment suggests a similarly obvious implication: dog owners tend to punish disobedient behaviors and refrain from rewarding them, at least not intentionally. The authors also found a strong correlation between punishment and the relative incidence of behavior problems. That the greatest number of problem behaviors were reported by owners using the most punishment or those combining punishment and reward, yields an obvious corollary of the foregoing, just as commonsense might predict, namely, owners of problem dogs are more likely to react with punishment or a combination of aversive and attractive means in an effort to control behavior problems. In contrast, dogs showing the least number of problems would naturally tend to receive more rewarding interaction—again an obvious finding, after all what would lead a sane person to shout or cause discomfort to their dog if it were not in reaction to some undesirable behavior.

The authors also found that dogs that walked obediently on leash were more likely to be praised by their owners than dogs that pulled, a finding that suggests that obedient dogs may have received some prior inhibitory training, perhaps combining leash jerking with praise, such as a method popularized in England by Woodhouse and widely practiced in one form or another in the United States. Praise and petting in the context of inhibitory training may serve to support consequent autonomic attunement and safety. Once limits are set on pulling, reward-based exchanges can, indeed, help to maintain obedient walking habits; however, praise-alone would hardly be an adequate incentive to prevent or stop pulling by normal dogs. The notion that average dogs might be trained by their owners to walk "at heel" in public by using a praise-alone technique is highly improbable. Practical experience dictates that a combination of techniques incorporating both attractive and aversive motivational incentives fitted to the individual dog's needs works best for controlling leash-pulling excesses and other behavioral complaints resulting from the incessant canine appetite for drive-activating stimulation and novelty that most dogs show when outdoors.

The authors appear to assume that the increased reward received by obedient and well-adjusted dogs carries the necessary implication that well behaved dogs are made that way by means of reward-alone methods—an approach that they claim was practiced by an astonishing 20% of their owner respondents. They also report that nearly 10% of dog owners used a punishment-only method of control. Logically, it is difficult to consider how reward-only or punishment-only training might be implemented, since by definition the contingent withdraw or withholding of an attractive event is punishing, just as the contingent withdraw or omission of an aversive event is rewarding. How an owner might be able to carry on everyday exchanges with the dog that only resulted in reward or punishment is hard to imagine. In general, the findings reported by Hiby and colleagues point to the obvious conclusion that highly excitable, impulsive, and disobedient dogs are more likely to receive more punishment than dogs considered by their owners to be relatively calm, well-behaved, and obedient to command—dogs that are more likely to become the object of affectionate appreciation. Here is the real welfare implication of their study,

viz., problem dogs are at greater risk of becoming the object of owner frustration, anger, and abuse.

Most dishearteningly, however, after acknowledging that their findings lacked causal significance (i.e., correlations of this sort do not prove cause-effect relationships), the authors nevertheless go ahead and treat them as though they were causally significant, concluding that reward-only methods represent "a more effective and 'welfare-compatible' alternative to punishment for the average dog owner" (2004:68). Instead of considering the most obvious and plausible implications of their findings, the authors draw upon a far less plausible generalization in order to promote what appears to be for them a foregone conclusion: aversives are *bad* for dogs and *good* owners and trainers should not use them. The authors appear to be so swayed by their heartfelt convictions and morality-speak regarding the "welfare-incompatible" implications of aversive training techniques that they entirely neglect to consider the most reasonable alternative hypothesis, namely, that aversive control efforts might actually offer significant welfare-compatible benefits. The oblique tone and pejorative commentary contained in this study also warrants mention. Not only is such diatribe demeaning with respect to the trainer's art and tradition, the particulars of the commentary are generally in conflict with a large body of practical and scientific evidence indicating that aversive motivational incentives can be effectively used in the context of reward-based training to enhance the human-dog bond and improve the dog's QOL.

The question is not whether aversives should or should not be used in the context of reward-based training; aversives *are* an integral aspect of competent dog training and aversive procedures will surely remain an instrumental and standard part of the dog trainer's practice (see Delta Society, 2002). What is more likely to change in a beneficial way is the relative reward-to-punishment ratio, the severity, and the frequency with which aversive procedures are used—a fairly constant trend that is evident in the tradition of dog training as well as in contemporary improvements and progress in training methodology and skills. The debate would be far more constructive if it focused on how such procedures might be most effectively and efficiently used to minimize adverse side effects while maximizing potential welfare benefits in the context of reward-based training. The humane use of dog training methods depends on trainer competency, which, in turn, depends on suitable experience and reliable scientific information—not the imposition of moralistic agendas opposed *on principle* to the use of aversive procedures in dog training.

Anthropic Dominance Ideation, Perceived Power, and Control Styles

Bugental and colleagues (1993) have studied the dominance dynamics between caregivers and children. This work provides a number of useful insights into dominance and its destructive influences on dependent familial relationships. The attribution of dominance to children (and dogs) appears to be the expression of an insecure cognitive bias affecting an individual's perception of the power dynamics between themselves and dependent others. The power ideation and narrative used by persons with low perceived power are often employed to rationalize the abusive behavior-control tactics that such low-power persons are prone to employ in order to control dependents. Low-power parents interpret challenging behavior as being determined predominantly by causes under the child's control (e.g., stubborn or dominant attitude) rather than being the result of causes under proactive parental control. The researchers found that, while observing child behavior perceived as challenging, low-power parents filter and interpret what they see in terms of threatening implications. The reactive bias shown by such parents is indexed by changes in autonomic activity consistent with defensive arousal and a vulnerability to form nervous/insecure attachments. In contrast, high-power parents perceive the causes of challenging behavior to be predominantly under proactive control and remain in a state

of autonomic balance while viewing challenging child behavior—a profile consistent with a capacity for autonomic attunement and the formation of secure attachments.

In addition to autonomic differences indicative of a reactive coping style and defensiveness, low-power parents show significant changes affecting dominance ideation when operating under the influence of cognitive load. Under cognitive load, low-power parents tend to exaggerate the power disparity between themselves and their children, tending to rank the child as being more dominant, and justifying deprivational, emotional, and physical abuses toward the child as *self-defense*. However, when these same low-power parents are not under the pressure of cognitive load, they appear to adopt an opposite attitude and estimation of social power relative to the child, tending to rank themselves as possessing more power than the child. These power-dominance vacillations inject a disruptive dynamic of ambivalence that increases the risk of gratuitous retaliation against the child (Bugental et al., 1997). Similar power dynamics appear to filter the way low-power owners and behavior modifiers interpret challenging dog behavior.

Whereas low-power behavior modifiers dwell on causes beyond their control, high-power behavior modifiers focus their attention and training efforts on matters that are within their reach and ability to change. The prominent findings of Bugental's research can be summarized and extended to behavior modifiers, as follows:

1. Low-power behavior modifiers are more likely to indiscriminately interpret challenging or oppositional behavior as a power contest beyond the reach of proactive behavioral interventions.
2. Low-power behavior modifiers are more likely to engage in highly intrusive or aversive deprivational, emotional, or physical practices.
3. Low-power behavior modifiers are more likely to interpret challenging and oppositional behavior in terms of malevolent social power intentions.
4. Low-power behavior modifiers unsure of their authority and power to control a dog in proactive ways are more likely to resort to coercive emotional tactics, abusive force, or deprivational strategies.
5. Low-power behavior modifiers tend to justify highly intrusive and aversive training activities by appealing to self-defense and public safety.
6. Low-power behavior modifiers are more likely to interpret and respond to the uncertainty of ambiguous situations as threats, causing them to respond with inconsistent and reactive punishment.

Recurrent cycles of passive resentment followed by reactive and abusive power assertions appear to activate social ambivalence and entrapment dynamics, perhaps inoculating the dog with anxiety, irritability, and social withdrawal (dispersive tensions) or activating incompetent and reactive autoprotective strategies for coping with the low-power owner's inconsistent behavior and uncontrollable mistreatment. Exposure to cyclical patterns of passive resentment and arbitrary social and emotional deprivation, excessive confinement and restriction, and uncontrollable physical punishment may infuse social interaction between the dog and offending family members with a high degree of conflict, uncertainty, and mutual mistrust (distrust), perhaps causing the children and the dog alike to adopt preemptive and autoprotective strategies for coping with the reactive power shifts governing the low-power owner's control efforts. Alpert and colleagues (2003) found that children of parents diagnosed with depression (low-power state) and comorbid anger attacks were more vulnerable to develop post-traumatic stress disorder (PTSD) or increased aggressive behavior than were children of parents diagnosed with depression without comorbid anger attacks. These patterns of increased autoprotective behavior of children appear to parallel the reactive coping styles shown by dogs exposed to a history of maltreatment and abuse by low-power owners. The same research group also found that children of parents with early-onset depression were more vulnerable to develop a variety of psychological and social disturbances (e.g., delinquency and aggression) than were children of parents with late-onset depression

(Petersen et al., 2003). These psychiatric findings suggest a possible linkage between dog owners affected by depression (low-power state) with anger and an increased risk of reactive/impulsive aggression and other challenging behavior problems in dogs—a hypothesis that might be used to test and falsify the antipredator/autoprotective account.

Low-power individuals appear to be prone to behave in ambiguous or impetuous ways toward the dog or send social messages having passive-aggressive implications that may contribute to social ambivalence and reactive adjustments. A dog owner that abruptly grabs a sleeping dog around its head to give it a firm kiss on the mouth is not performing an act of loving appreciation, but is tempting fate with arrogance standing on the shoulders of ignorance. The evident abandonment of common sense at such times is the sort of thoughtless and inconsiderate action that has frequently resulted in devastating bites. As demonstrated in the case of children (Bugental et al., 1999b), dogs also appear to *tune out* ambiguous social signaling. Unfortunately, in human-dog interactions, the disengagement of social and attentional resources in response to ambiguous social interaction may trigger autonomic arousal, executive, and physiological functions coordinated and attuned by selective and sustained attention.

The finding that persons prone to low-power estimations are vulnerable to distort and shift their perception of relative control depending on cognitive load appears to question the validity of questionnaires and self-reports for estimating the efficacy of aggression-treatment programs. Low-power owners, depending on the quality of emotional support provided during counseling, may subsequently judge their personal power over the dog in a highly inflated or deflated way. Consequently, the estimates of behavioral improvement that such owners may attribute to medications or behavioral treatments may be confounded with changes in their dominance ideation and perception of control rather than effects specific to the intervention, which may not actually exist (false positives) or may exist but are not recognized (false negatives). The work by Bugental and colleagues has obvious implications with respect to providing a theoretical framework for studying the effects of owner control styles on the differentiation of adaptive and reactive coping styles. Study of owner control styles would be relevant to cynopraxic theories of social aggression and separation distress, and might also have general implications for understanding how proactive and reactive behavior is shaped. In addition to needing a questionnaire validated for the detection and assessment of low-power and high-power dog owners, such research would likely benefit from a design in which between-group comparisons could be made of dogs meeting the criteria of stable versus unstable extraversion. A similar sequestering of dogs according to criterion of stable and unstable introversion might also be performed. How stable and unstable extraverts and introverts progress under the influence of owners with high-power or low-power control styles may reveal interesting relationships between the stable-to-unstable continuum and the owner's control style. The study might be revealing with respect to dynamics mediating adaptive and reactive coping styles and factors contributing to the integration of secure and insecure attachments. Topál and colleagues (1997), for example, have found that the problem-solving ability of dogs is inversely related to the strength of the dog's attachment to the owner (i.e., problem-solving abilities decrease as attachment measures increase), which is consistent with the notion that dogs with insecure attachments would be more vulnerable to interactive conflict and a reactive coping style. Finally, such research might be readily performed in the context of an animal shelter with the human questionnaire and canine personality testing performed as a routine part of the adoption process.

Power-dominance Ideation and Treatment Protocols

The power-dominance motivation attributed to canine domestic aggression is widely accepted as a leading cause of intrafamilial aggression. Appeal to social rank as a cause of aggression is a central theme guiding much of

the applied and popular dog behavior literature, with most authors rehashing the narrative account or tweaking it to justify their particular dominance-oriented treatment program. However, instead of helping family members to understand the causes of dog aggression, such emphasis on dominance and rank may serve only to perpetuate a malevolent interpretation of canine intent and purposiveness that places undue and inappropriate focus on causes that are predominantly beyond an owner's control and rarely significant for the treatment of domestic aggression problems. Instead of interpreting the etiology of intrafamilial aggression problems and their treatment in terms of adversarial hierarchical dynamics, counseling and training activities are better served by focusing on the antecedent events and establishing operations specific to interactive exchanges triggering reactive behavior, insofar as these behavioral elements are accessible and subject to change by means of social exchange.

The dominance narrative not only has obscured the causes of aggression problems but has also resulted in a considerable amount of conceptual confusion that continues paralyze research, concealing far more than it reveals by way of a simplistic explanation regarding the causes of aggression. The anthropic dominance bias frames an excessively myopic and simplistic perspective on canine social behavior, giving rise to circular diagnostic labels and treatment rationales based on the dominance narrative. The effects of this misconception are not just of theoretical interest, because the dominance narrative and unfounded assumptions arising from it are used to justify a variety of highly intrusive and aversive practices in the name of rational therapy. The dominance narrative frames autoprotective and challenging dog behavior in a manner that contributes to the use of abusive emotional deprivation, aversive physical control and restraint tactics, and unproven pharmacological and surgical procedures. A leading cause of ineffectual management and treatment is the habitual targeting coercive tactics at quashing the "dominant" dog's attitude or perception of rank. The default use of drugs to treat such problems is especially problematic because it appears to shift the domain of causation from the dog's attitude to its physiology—a domain of causality that is sufficiently vague for both the owner and the behavior modifier to promote magical thinking about the efficacy of such treatments.

Although some dogs with severe aggression problems may be victims of inadequate socialization and training, their care and training are frequently not that much different from the way many millions of other dogs are treated that do not develop aggression problems. Given the notable lack of (1) formalized-threat sequencing, (2) the severity of attacks, (3) the explosive and situational inappropriateness of attacks, (4) the benign nature of the provoking challenges or threats, and (5) the general incompetence exhibited by the aggressor and the victim, diagnosing such attacks as "dominance aggression" seems akin to pounding a square peg into a round hole and calling it a perfect fit. Most dogs with serious aggression problems do not appear to have been victimized by physical punishment. Instead, aggression seems to emerge under the influence of a genetic predisposition and the incubation of nervous or insecure attachments, interactive conflict and tensions, entrapment dynamics and social ambivalence, adverse dietary and environmental conditions, inadequate exercise and play, excessive confinement and restraint (isolation), suboptimal attention and tactile stimulation, autonomic dysregulation, or the absence of appropriate training and play. In short, as the result of an emergent reactive coping style, selective attention and impulse-control capacities may be degraded and impaired, causing the dog to become increasingly inattentive, uncooperative, aloof, or impulsive—attributes often claimed to be evidence of dominance problems.

These various issues stress the danger inherent to approaches that take anthropic ideas and symbols such as *dominance* and reify them into substantive causes or proximate relations in order to rationalize intrusive and aversive behavior-change procedures that ironically are not too dissimilar from the *real* causes of aggression. A substantive body of

human research indicates that perceived power and dominance ideation promotes a number of cognitive and behavioral effects on how parents, teachers, and caregivers cope and respond to the challenging behavior of vulnerable dependents (Bugental et al., 1993, 1997, and 1999a), findings that are directly relevant to how family members and professionals cope with the management and treatment of problem canine behavior. The designation of low perceived power or high perceived power is based on the relative importance that owners place on accessible and controllable behavioral causes versus causes that are predominantly under a child's control or causes that are perceived as being uncontrollable by both a dog and its owner (e.g., disease model). For example, the attribution of stubbornness as a cause of uncooperative behavior is an indicator of low perceived power, since the lack of cooperation is perceived predominantly as being under the control and intent of a stubborn dog or child. Similarly, consultants and trainers operating under the influence of a low-perceived-power construct may attribute a dominant attitude and other highly speculative causes to explain the etiology of aggression and challenging behavior. The tendency to attribute attitudinal causes associated with the dominance ideation may be linked with excessively intrusive or aversive training strategies or reliance on unproven nutritional or psychopharmacological protocols.

Low-power owners (like low-power parents with regard to their children) tend to explain their dog's misbehavior in terms of causes that lie outside of their control or understanding. The low-power behavior modifier may perpetuate this perception by searching for causes of the problem in the dog's attitude or distant history that resonate with the anthropic dominance myth. From the very outset of such therapy relationships, the dog's behavior may be framed in terms of power-ascendant motives and a preoccupation with finding ways to leverage power and control over it. Instead of highlighting how social ambivalence and inconsistent control efforts may have contributed to the problem, the counselor may assign an attitudinal cause to behavior and give the owner a diagnostic label with which to justify abusive deprivational and emotional treatment procedures that resonate with and confirm the owner's powerlessness. Unfortunately, by locating the causes of aggression in a dominant attitude or perception of rank, the trainer/consultant may only succeed in strengthening the owner's private distortions and belief, thereby perpetuating problematic power-dominance dynamics. The seeking and getting of a diagnostic label may tap a primitive urge to possess a magical name, causing a low-power owners or supplicant to seek out the wisdom of a low-power behavioral hierophant, hoping for a revelation, a magical name, a vision of the future, a potion, or a set of rituals with which to placate the mysterious forces causing the dog to misbehave. With the possession of a name, the low-power owner may feel empowered by virtue of the arcane scientific authority and significance attributed to it. Obviously, the practice of diagnostic labeling is extremely problematic, and especially so when the name shifts from a merely descriptive significance to causal significance; that is, the diagnostic label is no longer used to specify a collection of symptoms but now implies explanatory power to identify a physiological or phylogenetic cause. The interpretations used by low-power behavior modifiers are often little more than descriptive platitudes and elaborate myths that lack coherent causal significance. Unfortunately, the nominal fallacy (i.e., confusing naming with explaining) is widely committed in the context of treating canine adjustment problems.

The autoprotective perspective is more parsimonious and consistent with the collection of known facts than is the dominance account (see *Antipredatory Strategy and Autoprotection versus Dominance* in Chapter 8). Although an oversimplification itself, the antipredator hypothesis is a much less harmful over simplification than is the dominance myth. The antipredator model puts the owner in an instrumental role, thereby correctly emphasizing that human-dog interaction and, in particular, human action, rather than malevolent canine intent and power-dominance motivations, are the primary causes to

blame (if any) for domestic aggression; dogs, like most prey animals, rarely go out of their way to instigate aggressive contests, at least not without significant agitation and due cause for such anomalous behavior. In general, dogs are not in need of therapy to modify a distorted "perception of rank," but the dog and its owner may need to learn how to build relations conducive to cooperative exchanges and autonomic attunement while integrating secure social and place attachments. Like a dog living under social ambivalence and dispersive tensions, an abused child may also adopt an antipredatory orientation toward the parent and acquire the habits of a frightened prey animal but secretly harbor or surreptitiously act out fantasies of cruelty on the dog. As the child enters into power relations with other children and the family dog, the parent's predatory model may become apparent in the child's abusive and ambiguous relations with the dog, perhaps causing him or her to become increasingly exploitive and intrusive toward the dog while extracting pleasure from its distress and victimization. Children that treat dogs abusively and communicate ambiguous affection and play signals might, therefore, reflect some of the same dynamics expressed in the reactive behavior of the dog. The child and the dog may mirror and express similarly reactive behaviors, ambivalence, and impulsivity flowing from exposure to the same parental emotional or physical abuse.

The relationship formed between the owner and the behavior modifier appears to exert a profound influence on the owner's perception of control, depending on the nature of the causes (accessible versus inaccessible) attributed to the problem, and the treatment strategy selected to resolve it. The typical treatment strategy adopted is based on either a proactive open-stance orientation directed toward accessible causes or a reactive closed-stance orientation directed toward inaccessible causes (i.e., relatively uncontrollable or unknown). A major ethical and welfare consideration recommending the autoprotective account of canine domestic aggression is that it avoids evoking anthropic dominance ideation and the biased framing of challenging dog behavior in terms that encourage the use of abusive or ineffectual treatment programs aimed at coercing a change in the dog's "dominant" attitude or perception of rank. The dominance narrative is widely associated with the use of abusive emotional deprivation, traumatizing physical punishment and restraint tactics, and unproven pharmacological interventions.

The cynopraxic approach emphasizes counseling and therapy aimed at facilitating improved attention and impulse control, integrating affectionate and playful relations, supporting autoinitiated behavior and emotional autoregulation, and promoting a gratifying life experience—changes that naturally reduce the risk of domestic aggression. An important goal of cynopraxic counseling and therapy is to empower the owner with basic skills and dog sense to promote a fair balance of control and appreciation of the dog's needs, while improving the dog's ability to engage in interactive prosocial exchanges rather than resorting to reactive antisocial behavior. In particular, play represents a potent tool for adjusting the social imbalance contributing to impulsivity and reactive behavior. Comprehensive cynopraxic training and behavior-therapy efforts serve to promote changes that facilitate a functional equilibrium at virtually every level of behavioral organization. These social changes are brought about by the integration of secure attachments and an enhanced QOL that benefits both the dog and the family members.

Problematic Trends and Obstacles to Adaptive Coping and Attunement

In addition to avoiding training procedures that are needlessly aversive, cynopraxic trainers avoid procedures that intrude excessively upon a dog's freedom incentive (see *Hydran-Protean Side Effects, the Dead-dog Rule, and the LIMA Principle*). Training efforts that inappropriately restrict a dog's ability to initiate goal-directed behavior not only adversely impact the dog's QOL but often do so without contributing any real therapeutic benefit. For example, inappropriate restraint or isola-

tion, pointless deprivation procedures, intrusive rules of interaction, and tedious extinction and training rituals may be of little positive benefit with respect to training goals but impose time-consuming hardships on the owner, impede the bonding processes, and impair the dog's ability to adjust, perhaps making the problem worse. Although highly intrusive procedures do not generate physical pain, they can produce significant *emotional pain* and distress while augmenting interactive conflict.

Pharmacological Control of Behavior

In recent years, the introduction of a medical model of dog behavior has led some practitioners to treat adjustment problems as mental disorders having physical causes and often to emphasize the role of disease as the underlying cause of behavior problems (Mills, 2003). Although the medical model is not entirely without merit, as some valid parallels exist between certain psychiatric disorders and canine behavior disorders and undoubtedly some behavior disturbances are the result of disease, overly speculative assumptions, problematic diagnostic labels, and an excessive reliance on psychotropic drugs based on rationale borrowed from human psychiatry serve only to compound the current puzzlement regarding the etiology and functional significance of canine adjustment problems. In addition to emphasizing disease etiologies and the importance of drugs to treat behavior problems, many practitioners who stress the medical model claim special authority pertaining to matters of diagnosis whereby the "physical" causes of the problem are purportedly identified, usually by means of speculative inferences from emotional and behavioral signs. These putative but unproven physical causes are then targeted with various medications believed to mediate a resolution of the problem. Unfortunately, the various inclusion and exclusion criteria used to make behavioral diagnoses and related drug-treatment decisions tend to cause referring professionals and owners to defer treatment until the canine adjustment problem reaches a form that threatens the dog with relinquishment or euthanasia, rather than initiate behavioral treatment at the first sign of a problem. The pharmacological approach resonates with the low-power owner's basic assumptions, placing the causes of the dog's adjustment problems beyond the scope of conventional training and socialization efforts. The adjustment problem is encapsulated within an involuntary subdomain of physiology that places it outside of the dog's voluntary control and prevents its resolution without the help of drugs. In contrast, the cynopraxic approach views the physical changes to brain that mediate disturbance as the result of the accumulative effect of conflictive social exchanges and reactive adjustments in response to environments chronically lacking sufficient predictability and controllability to promote an adaptive coping style. Conversely, by changing interactive habits of social exchange to promote interactive harmony in combination with appropriate QOL changes that support the dog's needs, the physiological causes of disturbance are replaced by physiological changes conducive to adaptive optimization and social adjustment.

Although drugs are potentially useful in some refractory cases, the current state of the art remains investigational, and the ultimate benefits of drug therapy are uncertain, especially with respect to the control of domestic aggression problems (see *Pharmacological Control of Aggression* in Chapter 6). Even in the realm of human psychiatry, the efficacy of the most commonly prescribed mood-altering drugs used to treat anxiety and depression disorders has been questioned. Kirsch and colleagues (2002; see also Kirsch and Sapirstein, 1998), for example, who performed an extensive meta-analysis of treatment data submitted to the U.S. Food and Drug Administration (FDA) between 1987 and 1999, found that 80% of the clinical response of humans to six commonly prescribed antidepressants was duplicated in placebo control groups, suggesting that the selective serotonin reuptake inhibitors (SSRIs) tested may have little clinical effect separable from that of placebo. A remarkable neuroimaging study of human patients treated for depression has shown that placebo responders and fluoxetine responders

show similar changes in glucose metabolism in specific cortical and limbic areas, concluding that the "administration of placebo is not absence of treatment, just an absence of active medication" (Mayberg et al., 2002). In addition, the study revealed that the two groups responded differently to fluoxetine, with the drug producing specific changes in the hippocampus and brainstem of fluoxetine responders after 1 week of therapy that predicted a long-term response to the medication. Responders also showed a switch effect in response to drug therapy that resulted in an initial elevation of posterior cingulate metabolic activity followed by a decrease and then a gradual increase over the 6-week period of therapy—a pattern of change not exhibited by placebo responders. These distinct metabolic changes that differentiate responders from nonresponders suggest that tympanic temperature fluctuations might be present among dogs that could be tracked to help identify serotonergic responders from nonresponders (see *Functional Lateralization and Tympanic Temperature* in Chapter 9).

Although the FDA appears to enforce strict standards of efficacy to gain approval on certain classes of drugs, there appears to be a troubling double standard with respect to others, perhaps including the level of stringency applied to psychotropic drugs such as SSRIs. However, the most egregious and disturbing example of a double standard used to evaluate drug efficacy is the special and protected status afforded to homeopathic substances, described by one FDA representative as "kinder, gentler medicine" (Stehlin, 1996). Incredibly, homeopathic remedies are approved as drugs without meeting the rigorous standards of proven efficacy set for other drugs issued FDA approval. A meta-analysis of 89 studies using homeopathic substances to treat various medical conditions concluded, "Our study has no major implications for clinical practice because we found little evidence of effectiveness of any single homoeopathic approach on any single clinical condition" (Linde et al., 1997:840).

With regard to serotonergic antidepressants and dog behavior problems, even when apparently efficacious in the short term, aggression-controlling medications are unlikely to succeed in the long term without the support of complementary behavior therapy. The therapeutic use of social placebo is acknowledged as a valuable tool in the cynopraxic treatment of behavior problems (see *Social Placebo* in Volume 2, Chapter 10), but the administration of costly psychotropic drugs that exert potential health-threatening side effects for the sake of questionable benefits that do not rise above placebo alone raises serious ethical and welfare concerns. In any case, no drug or combination of drugs currently available can provide the sweeping range of dramatic and subtle balancing and integrative effects that are mediated by cynopraxic training and play therapy (see *Modulatory and Unifying Effects of Play* in Chapter 6). Comprehensive cynopraxic training and therapy efforts promote changes that facilitate a functional equilibrium at virtually every level of neural organization. Cynopraxic therapy is based on the assumption that social exchange promoting adjustments conducive to an adaptive coping style and secure attachments serve simultaneously to mediate physical alterations of the neuronal substrates mediating social ambivalence and reactive behavior. In particular, play therapy represents a potent tool for adjusting autonomic imbalance and reducing the allostatic load perturbing the complex feed-forward trafficking of neuronal networks that contribute to the etiology of adjustment problems (see *Cynopraxis: Allostasis, Adaptability, and Health*).

When drugs are used to manage intractable behavior problems, the goal should be to alleviate allostatic load and to promote neurobiological changes conducive to social affiliation and playfulness. Pharmacological efforts used merely to suppress undesirable behavior seem wrongheaded, violate the dead-dog rule, and are intrinsically problematic with respect to the basic bond and QOL tenets of cynopraxis. Dogs that engage in autoprotective behavior usually do so out of emotional extremis associated with chronic stress and allostatic load. Using behavior modification, restraint and isolation, emotional deprivation, or drugs to suppress undesirable behavior, without alleviating the underlying social and environmental causes

hindering a dog's ability to cope adaptively, violates basic welfare principles (Broom and Johnson, 1993).

Mechanical Suppression of Behavior

The restrictive loss of freedom imposed by excessive crate confinement is especially prone to cause harm in cases where the procedure is used in the absence of constructive training efforts; that is, where crate confinement is made into a way of life or a *steel straitjacket* for the purpose of preventing some undesirable behavior by mechanically suppressing all behavior. The word *crate* carries the implication of a temporary container used for the purpose of stowing an animal away, whereas the word *cage* has the added onus of being a permanent place of restrictive confinement used to control an animal's behavior, particularly an animal regarded as dangerous and untrustworthy. A cage serves to isolate and restrain an animal in a way that makes it constantly available for various exploitive purposes that are generally performed against its will, such as a spectacle for public viewing in zoos, for entertainment on a stage, or as an object of scientific investigation. Whereas a dangerous wild animal might be briefly crated for transport or medical treatment, its permanent place of confinement and isolation from other animals and people is a cage. In contrast, domestic animals are *housed* in pens, coops, stalls, and so forth, depending on the needs of the species and the uses made of the animal. In the case of dogs, long-term confinement generally involves the use of a kennel and adjoining run appropriate to the dog's size, an arrangement that gives the dog access to both indoor and outdoor environs to rest or move about freely and to eliminate away from its sleeping and eating areas. When a dog must be kenneled on a long-term basis, at a minimum the arrangement should include the company of another dog, preferably of a similar size, friendly disposition, and a compatible same or opposite sex companion. In designing and managing environments used for animal confinement, appropriate consideration should be given to making the living space compatible with species-typical social predilections and group-organizing tendencies. Of critical importance for the housing of dogs is the provision of adequate opportunities to engage in pack-coordinated activities, which require access to large open areas for social interaction. In the case of a dog living in a home, putting the dog in the backyard alone is inadequate with respect to social needs—space alone does not confer significant benefit. Social activity needs are nicely satisfied within in the home by the combination of daily training, tug-and-retrieve play, and neighborhood walks.

Many advocates of long-term crate confinement claim that dogs are phylogenetically preadapted to live in a crate. These conclusions are based on various fallacious assumptions derived from inappropriate comparisons with the use of dens by wild canids and feral dogs. In reality, a crate has far more in common with a trap (or grave) than it does with a den. Further, a den actually has far more in common with a home, the natural environment of a dog, providing access to communal indoor and outdoor living spaces via a two-way door. An obvious distinction between a den and a crate is physical entrapment, isolation, and inescapability. While the den provides the mother with the seclusion and security that she needs to deliver and care for her young, it does not restrict her freedom of movement, as the crate does. Instead of providing a safe environ for her young, the crate serves the express purpose of separating the dog from social attachment objects. Further, instead of promoting comfort and safety, the inescapable exclusion imposed by crate confinement appears to confer an increased vulnerability for disruptive emotional arousal and insecure place attachments. Most puppies and dogs show a high degree of aversive arousal when first exposed to crate confinement, which is consistent with the foregoing comparison. After learning that the crate is inescapable, however, dogs appear to treat the crate in a paradoxical manner analogous to persons affected by the Stockholm syndrome (Ochberg and Soskis, 1982); that is, they appear to form strong attachments with

the crate, which becomes the place they identify as home.

The primary motivation governing the use of crates is similar to the reason certain wild animals are isolated in cages; viz., a dog's freedom is perceived as representing some sort of threat or risk, usually in association with destructive habits or elimination problems. The daily ritual of cajoling and luring the dog into the crate may also gradually result in the dog acquiring a growing mistrust toward the owner, as reflected in its refusal to cooperate in other ways not directly related to confinement. The widespread practice of routinely caging a dog at night and then again during the day for periods totaling 16 to 18 hours (or more) is an extremely problematic practice that should not be condoned or encouraged, because it probably underlies the development of many adjustment problems, including aggression.

For many pet trainers, pet-trade breeders, and like-minded veterinarians, caging is frequently promoted as a humane alternative to more time-consuming and skill-intensive training efforts. Although crate confinement can be a useful asset when integrated into a competent training program, to expose a dog repeatedly to 16 to 18 hours of daily caging makes no sense. The fact that a dog can survive many months of such solitary confinement in a space barely big enough for it to turn around is testament to its flexibility. In addition to crate confinement, various devices are used to supplement intrusive control efforts, such as muzzles used to restrict barking, thereby extending mechanical control over the dog's vocal behavior while it is in the cage. In other cases, owners use various behavior-activated collars designed to deliver a deterrent spray or electrical charge to control undesirable behavior while the dog is inside the crate. To restrain compensatory excitability and impulsivity, some ill-informed advisers might further recommend that the owner stop all play activities, especially tugging and roughhousing. To complete the picture, the owner may be sold on homeopathic remedies and vitamin supplements, fragrant odors and pheromones, or flower essence drops put in the dog's water to help reduce its stress!

Cynopraxis: Allostasis, Adaptability, and Health

At every step in a dog's ontogeny, predictive relations are refined and integrated into a base of genetic and experiential *prior knowledge*. These predictive relations are organized to promote stability through change, referred to as *allostasis* (Sterling, 2004). Allostatic adjustments enable dogs to anticipate and avoid future risks to stability, thus enhancing adaptive efficiency by responding to predictive signals. The genes that regulate neuronal activity depend heavily on experience for the information needed to maintain the brain's functional stability and capacity for coping proactively with change. The feed-forward unfolding of genetic information via experience-dependent gene activation and suppression is consistent with the notion that regulatory genes are responsive to positive and negative prediction-error signals. Consequently, causing neuronal activity to increase or decrease results in the production of structural proteins and enzymes, and thereby alters the neurophysiology in the process of mediating allostasis (Sterling and Eyer, 1988). Thus, the process of emergent individuation is seamlessly interwoven into a multitude of neurobiological changes that mediate cognitive, motivational, and behavioral adjustments. During such accommodation and allostatic change, the activation of neural protein synthesis and synapse building serves to integrate predictive information into the physical substance of the organism, leading to far-reaching benefits or harm influencing not only behavioral adaptation but also biological adaptation. By such means, *knowledge* acquired by experience is directly integrated into the neurobiological phenotype from where it exerts numerous adaptive and maladaptive effects on the developing organism (Kolb and Whishaw, 1998).

Acute stress is triggered in response to the detection of discrepant events that exceed the normal *safe* range of accustomed variability in combination with a perception of uncontrollability; that is, stress is a biological response to the violation of expectancy or a failure to establish predictive control over significant motivation events. Such events elicit intense state arousal, active vigilance, and increased

action readiness in anticipation of reactive emergency or defensive adjustments. Thus, chronic and uncontrollable challenges (loss of comfort), threats (loss of safety), and unconditioned aversive events mismatching prediction-control expectancies promote stress and allostatic load that adversely affect a dog's adaptability. Chronic exposure to aversive conflict situations perceived as uncontrollable tends to become increasingly problematic when they are also inescapable. Allostatic load associated with social ambivalence and entrapment is hypothesized to orchestrate widespread neuronal changes and emotional disturbances that adversely affect selective attention and impulse control.

Under social and environmental circumstances where a balance of predictive exchange is lacking, the ensuing instability and allostatic load make the work of adaptation increasingly costly. A failure to integrate a mutually satisfying household relationship based on predictable and controllable relations is not only disruptive at the level of social exchange—the consequences of such influences impact at various levels of a dog's biology and may gradually impair its capacity to adapt. According to cynopraxic theory, many maladies affecting canine health and well-being are traceable to dis-ease associated with chronic interactive conflict and compensatory allostatic load adversely impacting critical biological systems necessary to sustain health and survival fitness (see *Immune Stress and Cytokines* in Chapter 6 and *Stress, Thyroid Deficiency, Hypocortisolism, and Aggression* in Chapter 8). As such, cynopraxic therapy serves to promote both behavioral and biological stability by mediating changes that reduce interactive conflict and promote mutual appreciation and interactive harmony while enhancing the human-dog bond and improving the dog's QOL. The capacity of cynopraxic therapy to promote beneficial changes depends on the integration predictive control relations mediated by social exchange and transactions governed by a principle of fairness promoting mutual reward, cooperation, and affectionate playfulness between interactive partners around points of common interest and potential conflict.

Hydran-Protean Side Effects, the Dead-dog Rule, and the LIMA Principle

Aversive procedures are legitimate and valuable tools for controlling undesirable behavior, but such techniques can be rapidly debauched into a form that substantially complicates matters. Technically, punishment results when established control expectancies are disconfirmed, for example, when the trainer discontinues an attractive or aversive contingency. Punishment occurs when the dog recognizes that some previously successful action no longer controls the occurrence of some attractive or aversive event. Severe and sustained aversive stimulations in the absence of options to escape (e.g., beating) are of no use in dog training and for whatever reasons such nasty actions are performed they are likely to foster a far worse problem.

Just as chopping off the mythical Hydra's head only caused her to sprout more monstrous and threatening replacements growing out of the severed stump, the use of inappropriate physical punishment, restraint, and manhandling may only serve to stimulate autoprotective behavior and initiate various unanticipated vicious-circle effects. In such cases, the escalation of conflict and aversive arousal evoked by severe physical punishment may cause difficult behaviors to transform into even worse forms, especially in cases where the root causes of the problem are left unresolved. Homer's story of Proteus illustrates other aspects of potential harm wrought by inappropriate punishment and interactive conflict. For ancient seekers wishing to foresee the future, the water divinity had to be seized and held tightly as he morphed through a frightful array of threatening forms, until he finally gave in and returned to his normal form to give prophecy. The myth has obvious positive implications related to the constructive use of response prevention and blocking techniques, but more importantly with respect to the present topic, the myth resonates symbolically with the adverse effects of interactive struggles and tensions around points of conflict where the future is left uncertain until the conflict is resolved. Actions that emerge in the context of persist-

ent conflictive exchange are often highly reactive and pose many significant training challenges and risks. Further, as a result of a history of contentious interaction, dogs and people may gradually lose their capacity for mutual attraction and tolerance, becoming increasingly ambivalent, intolerant of uncertainty, and reactive toward the ordinary losses and risks associated with social exchange. Instead of engaging in friendly cooperation, the owner and dog may engage one another as adversaries in the process of morphing a veritable pantheon of adjustment problems out of the toxic conflict dynamics that bind them together.

All variation in canine social behavior develops in the context of coping styles emerging in various ways around interactive conflict. As such, the intersection of human and canine control vectors define the field of interactive possibility. Only by working through conflict by holding protean advantage-seeking efforts at bay and by opening a space of fair exchange and mutual appreciation around conflict situations can the other be perceived as a cooperator rather than a dominator or exploiter. With the restoration of *normal exchange*, the unifying relations and governance needed to promote an adaptive coping style can be pursued as a harmonious social space is extended over the field of conflict situations.

Despite obvious limitations and risks, aversive procedures are a necessary aspect of dog training and behavior-problem solving that cannot be neglected or substituted for (e.g., by drugs) when competent inhibitory control over highly motivated behavior is being established. These procedures are of great value in the context of basic training, the treatment of adjustment problems, and the integration of secure attachments. To maximize the benefits and to minimize the adverse effects of training procedures that compel dogs to act or not act in particular ways, two general guidelines appear to be useful: the least intrusive and minimally aversive (LIMA) principle and the dead-dog rule. The LIMA principle addresses the excesses and abuses that might arise when aversive or intrusive dog-training procedures are implemented. As such, it applies to both positive and negative punishment, and covers procedures that generate states of emotional pain and deprivation (e.g., long-term cold shouldering, crate confinement/isolation, and various restraint techniques). The LIMA principle entails that trainers use the least intrusive and minimally aversive technique likely to succeed in achieving a training objective with minimal risk of producing adverse side effects. Essentially, the LIMA principle is a competency criterion, since only competent trainers possessing the necessary know-how can make the required assessments and have the skills needed to ensure that the least intrusive and aversive procedure is in fact used. To speak of the effective and humane use of dog-training procedures in the absence of competency criterion borders on the ridiculous. Accordingly, incompetent uses of attractive and aversive motivational stimuli to modify dog behavior are liable to produce harmful effects that violate the dog's interests and breech the trust of the responsible dog owners seeking help.

A second general guideline that promotes the effective use of training procedures is the dead-dog rule, which recommends that training criteria and objectives be defined in terms that a dead dog cannot satisfy (see *Dead-dog Rule* in Volume 2, Chapter 2). In essence, the dead-dog rule is a complementary logic for framing the LIMA principle. By converting training goals into affirmative statements and identifying objectives that can be achieved only by a live dog, the resultant perspective is biased toward reward-based training efforts. For example, instead of training a dog not to bite (dead dogs do not bite), the dog is trained to be friendly and trusting, that is, to show affectionate, cooperative, and playful behavior incompatible with aggression—behavior that a dead dog cannot do. In the case of aversive motivational stimuli used in the context of aversive inhibitory control, the training objective is best described in terms of positive behavioral change that places the primary emphasis on escape-avoidance adjustments and the establishment of a *training space*, based on the acquisition of predictive information and a socially acceptable *escape-to-safety* response that result in reward. When properly performed, all training is reward based insofar as the dog learns how to control attractive and aversive events while negotiating conflict. In the context of reward-based

training, the dead-dog rule and the LIMA principle provide general guidelines for the use of attractive and aversive motivational stimuli to modify dog behavior (see *Compliance* in Volume 2, Chapter 2). When aversive procedures are used, the trainer should possess an objective rationale and the skills necessary to implement the procedures safely and effectively. The suppression of behavior by means of inhibitory procedures is appropriate and useful when regulating behavior governed by an excitatory imbalance and impulsivity but only to the extent that it is performed in the context of coordinated reward-based activities aimed at filling the void.

Cynopraxic trainers acknowledge and respect the dog's preference for pleasure by advocating the use of procedures that utilize reward and minimize punishment. However, to train a dog to a reasonable degree of reliability, the use of both attractive and aversive motivational incentives is an inescapable fact of life. In an important sense, reward and punishment are not properties of motivational stimuli or evoked attractive or aversive states but rather flow from the dog's ability to produce outcomes that either meet or exceed prediction-control expectancies. Training is not about making dogs feel good or bad—rather it is about enabling them to adapt well.

Appendix A

Sit-Stay Program

Modified Sit-Stay Instructions

Sit-stay training fosters competent skills for obtaining reward and avoiding its loss by training the dog to defer, wait, and relax in the process of seeking rewards. Sit-stay training is integrated with play, providing an additional source of reward and balance. In addition to affectionate petting and attention, sit-stay behavior is reinforced with food rewards of variable size, type, and frequency. The schedule and duration of stay periods also has a potentially rewarding effect on stay behavior. That is, once a standard expectancy is established, comparatively short stay periods may be conducive to reward via surprise. On the other hand, longer-than-usual stay periods may produce punitive effects that are inimical to sit-stay objectives. As a result, stay periods should only be gradually increased in duration and arranged to occur so that longer ones are followed by a series of shorter ones, play, or other sources of positive surprise (e.g., better-than-usual food rewards). Stay-training sessions are generally begun with short-stay periods, followed by a mix of variable duration periods in between, and finished with a long-stay period at the end. Each session is introduced and concluded with a period of play.

The initial lesson consists of training the dog to come to a closed hand after retrieving a ball or simply coming in the case of dogs showing little interest in ball play (see *Introductory Lessons* in Chapter 1). Just before the hand is opened, the bridge signal "Good" is spoken in a playful tone. The ball is taken and tossed for the dog to retrieve. Dogs that are uninterested in fetching a ball are permitted to explore the training situation freely between trials. Additional trials are initiated by calling the dog's name and making a smooch or squeaker sound after the dog picks up the ball, thus evoking an orienting response. As the dog turns in the direction of the trainer, the trainer can deliver a click and then flick the right hand to the side. The vocal signal "Come" is spoken in a friendly and encouraging way, followed by the voice bridge "Good" and the delivery of the reward concealed in the right hand. After each exercise, the dog is encouraged to retrieve a ball or move away with the release signal "OK" and a clap or two.

Improved orienting behavior can be achieved by putting a squeaker bulb in the right hand (held by the last two fingers), and squeezing it just as the dog approaches the hand. The bridge "Good" is spoken just before the hand is opened. In addition, an odor (orange or orange-lemon mix) can be placed in the squeaker, thereby establishing a linkage between the odor, squeaker sound, and food. As the result of repeated associations between the squeaker and food, the squeak sound acquires an enhanced potential for evoking an orienting response. Bridging the occurrence of the orienting response with a click and treat can further improve attention control. Olfactory conditioning is included in sit-stay training in cases where a platform for counterconditioning and desensitization is being prepared (see *Systematic Desensitization* in Chapter 3 and *Olfactory Conditioning* in Chapter 6).

With the dog coming rapidly to the closed hand, the trainer encourages the dog to sit by moving a hand up and behind the dog's head, causing it to follow and sit. The sit response is

reinforced with the bridge "Good," which is timed to coincide with the earliest movement in the direction of sitting. The sit response should be well trained to a hand signal before a "Sit" signal is added as a cue or command. The easiest way for most dogs to learn how to sit on command is to pair the "Sit" signal with a hand signal. The vocal signal is only paired with the hand signal after the dog is sitting consistently in response to the hand movement. If the dog fails to sit in response to the vocal cue, the hand signal is used to prompt the response. The trainer should avoid repeating the "Sit" command, but instead should use the hand to lure the dog into position, if necessary. The dog should gradually learn to sit equally well to both vocal or hand signals, but normally the signals are presented together. Although physical prompting, fading, and shadowing procedures are ordinarily used to increase reliable stimulus control over sit-stay behavior, these techniques are generally avoided with the goal of training the dog to defer without resorting to force of any kind.

Each successful sit response is rewarded, and additional rewards are given to the dog after varying durations of waiting in the sit position. The duration component of stay training is accomplished in the context of shaping an attending response. With the dog sitting in front, the trainer makes a smooch or cluck-click sound to encourage the dog to look up at the trainer and then to make eye contact before saying "Good" or clicking and delivering a food reward and affectionate pet. During such training, the trainer should make a friendly face expressing pleasure at the dog's effort and keep the training session upbeat and fun spirited. Initially, the bridge is timed to occur immediately as the dog looks up, but gradually requires that the dog hold eye contact for 1 or 2 seconds. As the dog learns to look up into the trainer's eyes, its name is presented just in advance of the smooch or cluck-click sound, a prompt that is progressively delayed and gradually faded altogether, but reinstated as needed to capture the dog's wavering attention. After every trial of attention training, the dog is released with "OK" and a clap or two. If the dog breaks the stay position, a brief unrestrained time-out (TO) or rest period of 15 seconds is initiated during which the dog's efforts to obtain food or attention are ignored. The dog is signaled by name to orient, to come, and to sit in accord with a previously mastered criterion that the dog is likely to perform successfully, even going back to conditioning the bridge signal, if necessary.

Distance is gradually introduced after a high degree of reliability is established over the duration element with the dog both in front and on the left side. With the dog looking up, the trainer presents the right hand, palm toward dog, and vocally praises the dog as it continues to stay in place, followed by a food reward and release. The vocal signal "Stay" is subsequently paired with the hand signal as the trainer takes a 1-foot step back, bridges the stay response, and quickly returns to the dog to reward it. This process is repeated a number of times with variable durations without releasing the dog. The dog is trained to expect additional rewards to follow rather then learning to get up in anticipation of being released. If the dog breaks without being released, a 15-second TO-rest period is initiated. Reliable stay at increasing durations and distances is achieved over several sessions. If at any point in the process the behavior breaks down, the trainer should go back to a previously successful step and continue from there. The duration of sit-stay sessions varies according to the dog's needs and motivation, but should be periodically interrupted with ball play or other play activities. Stay training can be repeated several times during the day in different locations around the house. Once a high degree of reliability is established over duration and distance control, an element of increasing difficulty and distraction can be added in accordance with sit-stay program criteria (see *Stay Training* in Chapter 1).

Dogs that repeatedly break the stay position may benefit from response blocking (e.g., active-control line) and vocal prompts ("Eh, eh"); however, stern reprimands, directive prompts, or forceful handling should be avoided. The goal is to train the dog to sit and stay to obtain attractive rewards and

avoid their loss. When gentle vocal prompting is used, it should be applied to the earliest intentional movements rather than applied after a dog breaks. An active-control line can be effectively used to help prevent unnecessary errors by training a dog to first stand-stay and then returning to sit-stay training. If a dog breaks completely, a brief TO-rest period follows during which the dog is ignored. If the dog barks during sit-stay training, the barking response should be brought under stimulus control. Jumping up should be treated in a similar way (see instructions for bring barking and jumping up under stimulus control in *Hyperactivity and Social Excesses* in Chapter 5). Once under adequate stimulus control, the opportunity to bark or jump up can be used as a reward. In the case of highly disruptive behavior, the trainer can leave the training room with the dog left on the other side of the door with the leash pinched in the doorjamb. The time-out lasts for 30 seconds provided that the dog has not scratched or barked for at least 10 seconds.

Once the sit-stay is mastered, a similar pattern of control is established involving down-stay training. Whereas the sit-stay is practiced with the dog in front and at the left side, the down-stay is practiced exclusively with the dog at the left side. In addition to luring and shaping techniques as described in Chapter 1, the down module can be trained by using an attention-cuing procedure. In this case, the trainer establishes eye contact and then glances at a point just in front of the dog. A constant gaze is fixed on the spot as the trainer steadily points and then taps over it. If the dog fails to lie down, the trainer looks at the dog, establishes brief eye contact, and then glances back at the spot and repeats the pointing-tapping procedure. As the dog begins to lie down, the bridge "Good" is delivered, followed by a treat after the action is completed. Many dogs resistant to lying down by other methods are often surprisingly responsive to this technique. Alternatively, a small square of cotton adhesive tape or Band-Aid is scented and presented to the dog to sniff and paired with food several times. The scented Band-Aid is then taped to the floor. The same attention-cuing procedure as described previously is used to train the dog to orient and sniff the scented tape and then to lie down. The scented tape can be gradually placed at greater distances from the dog. Again, the trainer makes eye contact with the dog, breaks it off to glance toward the scented tape, and then points at the spot. The dog is encouraged to go to the spot and sniff (click), wait there or lie down in response to a pointing-tapping action ("Good" and reward), and required to stay until it is released ("OK" and clap). In one variation, the pointing-down signal is gradually faded, and the dog learns to lie down in response to the scented tape alone. The scented tape can be affixed to a variety of objects that are left in plain view or hidden for the dog to find, perhaps becoming the basis of an interesting game for dogs possessing a proclivity for such activity. Procedural variations based on the spotting technique can be used in a variety of training applications requiring a precise search and down-stay component.

The various daily sit-stay skills listed in Figure A.1 represent a guide, not a rigid program. Instead of practicing all of the tasks listed for a particular day, trainers should limit practice activities to as many items as the dog can successfully learn and perform without becoming overly stressed. The goal of sit-stay training is to establish control while encouraging a set of positive secondary emotional associations with the training process, in particular imbuing the act of sitting and staying with feelings of to enhanced comfort, safety, and relaxation. In addition to benefits for dogs, reward-based sit-stay training can be helpful to owners by introducing the rudiments of training and opening up a new perspective on behavioral change and control. By avoiding coercive techniques, family members are obliged to learn more positive strategies and ways to affirmatively frame the dog's behavior (e.g., the dead-dog rule) and to use reward more effectively. While training the dog to sit and stay, a new level of appreciation for the dog's abilities and needs may be engendered. Finally, as the result of using a reward-based method, even briefly, owners may learn to think more clearly and rationally about the process of mediating behavioral

Dog's Name: Date:

SIT-STAY TASKS

PRELIMINARY SIT TRAINING	DIFFICULTY RANK 1–5	NO. TIMES REPEATED
The dog sits for a food reward		
The dog sits quietly for 5 seconds		
The dog sits quietly for 10 seconds		
The dog sits quietly for 15 seconds

Sit while you leave the room for 10 seconds		
Sit while you leave the room for 20 seconds		
Sit while you walk around the dog		
Sit while you leave the room for 10 seconds and walk around dog when you return		
Sit while you leave the room for 15 seconds and circle the dog when you return		
Sit for 5 seconds		
Sit while you circle the dog twice		
Sit while you walk 15 feet to the left, run 15 feet past the dog to the right, and walk back		
Sit and repeat the above		
Sit while you do the above in the opposite direction		
Sit for 5 seconds		
Day 7: The dog should		
Sit for 5 seconds		
Sit for 10 seconds		
Sit for 5 seconds		
Sit while you step back from the dog, sit down, and return		
Sit while you step back 5 feet from dog, sit down for 5 seconds, and return		
Sit while you walk across the room, sit (on a chair) for 15 seconds, and return		
Sit for 5 seconds		
Sit while you walk briskly 20 feet to the right away from the dog and return		
Repeat the above to the left		
Sit for 5 seconds		
Sit for 30 seconds		
Sit while you walk around the dog twice		
Sit while you take 10 steps briskly backward and then toward		

the dog		
Sit for 10 seconds turned away from the dog		
Sit for 20 seconds		
Day 8: The dog should		
Sit for 5 seconds		
Sit for 10 seconds		
Sit for 20 seconds		
Sit while you leave the room for 10 seconds		
Sit while you leave the room for 15 seconds		
Sit for 5 seconds		
Sit for 30 seconds		
Sit for 10 seconds		
Sit while you run 15 feet to the left and then to the right and back		
Sit while you do the above in the opposite direction		
Sit for 10 seconds		
Sit while you walk 10 feet away, circle the dog, and walk back		
Sit while you repeat the above at a brisk walk		
Sit while you circle the dog at 10 feet at a brisk walk		
Sit while you circle the dog at a brisk walk twice		
Sit for 10 seconds		
Sit while you leave the room for 10 seconds		
Sit for 5 seconds		
Sit while you circle the dog at 10 feet away		
Sit for 30 seconds at 5 feet away		
Sit for 10 seconds while 5 feet behind the dog		
Day 9: The dog should		
Sit for 10 seconds		
Sit for 60 seconds		
Sit for 10 seconds		
Sit while you circle the dog		
Sit while you leave the room for 10 seconds		
Sit while you back up 10 feet, sit down for 15 seconds, and return		
Sit while you circle the dog at 10 feet at a run		
Sit while you circle the dog twice at a run		
Sit while you reach for your toes		
Sit while you touch your toes twice		
Sit while you walk 15 feet to the right and then left before returning		
Sit while you do above in the opposite direction		
Sit for 10 seconds		
Sit for 30 seconds while you sit 5–10 feet away		
Day 10: The dog should		
Sit for 5 seconds		
Sit while you back up 10 feet and circle the dog at a brisk walk		
Sit while you walk to a chair and sit down for 10 seconds		
Sit while you walk to a chair sit down for 20 seconds and return		
Sit while you walk 20 feet to the right and run past the dog to		

20 feet to the dog's left and walk back		
Sit while you do above in opposite direction		
Sit for 10 seconds and both of you sit for 60 seconds		
Sit while you walk to a chair, sit for 10 seconds, walk briskly to 10 feet past the dog, and return slowly		
Sit while you repeat above		
Sit while you repeat above at a jog		
Sit while you repeat above at a fast jog		
Sit for 10 seconds		
Observations:		

change, thereby becoming less reliant on punishment and adopting a more constructive and balanced approach to their dog's training. As control over the sit-stay module is established, family members can be encouraged to integrate it into everyday activities possessing reward value for the dog.

Encouraging owners to keep a journal and other records associated with sit-stay training can help them to become more aware and objective with respect to their dog's behavior—changes of viewpoint that are particularly important in cases involving serious adjustment problems. The dog's response to sit-stay training and daily progress should be tracked by keeping a record of daily training activities. The relative difficulty of each sit-stay requirement is estimated by the owner in terms of a five-point scale between 1 (easy: almost without error) through 5 (difficult: dog made many mistakes). The owner should jot down each day of exercises on a separate sheet of paper, giving space for notes and detailed observations about the dog's response to sit-stay training. Later, the estimated relative difficulty is recorded on the master sheet, along with a letter grade (+A-, +B-, +C-) based on overall working attitude and the number of times that the response had to be repeated to reach criteria. In addition to estimating the difficulty for the dog and performance grading, the time of day, situational variables (e.g., distractions), motivational state (e.g., before or after meals), adverse influences, positive secondary changes, and so forth should be noted. Owners should be encouraged to write down their concerns and successes, thereby helping them to think more clearly about the dog's response to training projects.

Note: The foregoing instructions are in large measure consistent with Voith's intent and include some specific items that she included in her original instruction sheets (Voith, 1979); however, the procedures deviate in several significant ways from her original instructions.

Sit, Down, Stand, and Stay Practice Variations

Dog's Name: Date:

SIT VARIATIONS

Exercises Session	1	2	3
Sit with hand signal only			
Sit with voice signal only			
Sit from stand position after 3-second stay			
Sit from down position after 5-second stay			
Quick-sit while controlled walking			
Sit after starting exercise and 10-second stay			
Sit with the trainer in front after making and holding eye contact for 2 seconds			
Sit after the dog moves from the trainer's left side to the front			
Sit with the trainer behind the dog after 3-second stay			
Sit with the dog to the right after 10 seconds			
Sit with the trainer crouching			
Sit with the trainer sitting on the ground			
Sit with the trainer lying on the ground			
Sit while the trainer walks by at 3 feet away			
Sit while the trainer walks 5 feet away			
Sit from a stand at a distance of 3 feet			
Sit from stand after interrupted auto sit			
Sit from down position at a distance 5 feet			
Sit from a separate room			
Sit while another dog walks by			
Sit before a ball is tossed			
Sit at 10 feet away before a ball is tossed			
Stay and sit after a ball is tossed; dog is then released to chase the ball			
Sit after the dog turns around and stays 5 seconds			
Sit after moving to the right			
Sit after moving to the left			
Sit before jumping through a hoop or over a hurdle			
Quick-sit in the presence of a strong distraction (e.g., a squirrel)			
Quick-sit before a ball is tossed

DOWN VARIATIONS

Exercises Session	1	2	3
Down from sit with hand signal only			
Down from sit voice signal only			
Down from starting position after 5-second stay			
Down from the stand after 10-second stay			
Down from sit in front after 15-second stay			
Down from sit with the trainer to the left			
Down from sit with the trainer behind			
Down from sit with the trainer turned away			
Down from sit with the trainer crouching			
Down from sit with the trainer sitting on the ground after 10-second stay			
Down from sit with the trainer lying on the ground after 5-second stay			
Down from stand with the dog in front			
Down from stand with the dog to the right			
Down from stand with trainer behind the dog			
Instant-down			
Down from sit at a distance of 3 feet			
Down from sit from a separate room			
Down from sit at a distance 5 feet after 15-second stay			
Down from sit as another dog walks by			
Down from stand while another dog walks by			
Down from sit before the dog is released to chase a ball			
Down from sit after a ball is tossed; the dog is then released to chase the ball			
Down at 10 feet away before a ball is tossed			
Down after turning around			
Down on recall			
Down from sit after moving to the left			
Down after jumping through a hoop or over a hurdle			
Down from sit while near traffic			
Instant-down while running along side the trainer

STAND VARIATIONS

Exercises	Session 1	2	3
Stand with one step forward			
Stand with voice signal only			
Stand from the starting position after 5 seconds			
Stand from the down after 30 seconds			
Stand from sit with the dog in front after 10 seconds			
Stand from down after 45-second stay			
Stand from sit with the trainer behind the dog			
Stand from sit with the trainer turned away			
Stand from down with the trainer crouching			
Stand from sit with the trainer sitting on the ground			
Stand from sit with the trainer lying on the ground			
Stand from down with the trainer in front			
Stand from down with the trainer to the left			
Stand from down with the trainer behind			
Stand after instant-down			
Stand from down at a 5 feet away			
Stand from down as another dog walks by			
Stand from sit at a distance 5 feet near a busy corner			
Stand from down with hand signal at a distance of 10 feet after 30-second second stay			
Stand from sit while another dog walks by			
Stand from down at 5 feet away before the dog is released to chase a ball			
Stand from sit after a ball is tossed; the dog is then released to chase the ball			
Stand from down at 15 feet away before tossing a ball			
Stand and stay after turning around			
Stand from down after drop on recall			
Stand from sit after moving to the left			
Stand after quick-sit and 10-second stay			
Stand after instant-down and 30-second stay			
Walking stand-stay while alongside the trainer

SIT, DOWN, AND STAND COMBINATIONS

Exercises	Session 1	2	3
Stand and stay for 10 seconds			
Sit from stand with voice and hand signal			
Down from sit after 5-second stay			
Sit from down after 5-second stay			
Stand from sit after 5-second stay			
Stand stay for 10 seconds 5 feet away			
Sit-stay for 20 seconds 5 feet away			
Down-stay for 30 seconds 5 feet away			
Walking stand-stay and then facing the dog at 5 feet away for 10 seconds			
Sit from stand at 5 feet away			
Down from sit at 5 feet away			
Sit from down at 5 feet away			
Stand from sit at 5 feet away			
Starting exercise with auto sit from the left side			
Starting exercise with stand interruption			
Starting exercise to heeling w/o auto sit			
Starting exercise, auto sit, and stay for 30 seconds for recall, front sit, and finish to the left side			
Walking stand-stay to starting position and auto sit after 10-second stay			
Starting exercise to auto sit, sit-stay, and 10-second stay before down and sit from down at a distance 15 feet			
Sit-stay for 30 seconds at 20 feet to recall, sit-front, and finish to right side			
Starting exercise to auto sit, down, and stay for 1 minute at 15 feet away before returning and dog is released to fetch a ball			
Sit, down from sit, stand from sit, and stay for 20 seconds at 15 feet away			
Down from stand at 20 feet, followed by stand from down after 1-minute stay			
Walking stand-stay, sit, and down from 10 feet followed by 30 seconds			
Drop on recall, sit from down, and stand			
30-second stand-stay followed by ball play			
1-minute sit-stay followed by ball play			
5-minute down-stay followed by recall and finish from 20 feet away			

Observations:

FIG. B.1. Practice variations: sit, down, and stand. These tasks are intended as a general guideline. They should be gradually mastered and practiced in progressively longer and more difficult sequences. Many of the tasks depend on a well-established stay response that has been made reliable by sit and down-stay training. Tasks practiced are checked off after every daily session.

Appendix C

Posture-facilitated Relaxation (PFR) Training

Basic Guidelines and PFR Techniques

PFR training can be beneficial for puppies and dogs exhibiting a variety of adjustment problems. Of course, special precautions must be taken in the case of potentially aggressive dogs. Before being exposed to PFR training, such dogs should receive appropriate attention and integrated compliance training, and preliminary graduated counterconditioning as needed to reduce excessive reactivity to touching and handling. Adult dogs should be cautiously introduced to the procedure and may require a muzzle if they show signs of aggressive reactivity. The trainer should always be aware of the potential risks involved and error on the side of safety when performing such procedures, especially in the case of physically powerful dogs with a history of aggressive behavior.

Environmental Considerations

1. PFR training is first introduced in familiar situations with few distractions, but as a dog's relaxation response improves, it can be performed under more distracting and potentially stressful conditions. In the case of dogs exhibiting separation-related problems, massage should be performed in the room where the dog is left alone.

2. PFR training should be performed at times of need for de-arousal and increased relaxation.

3. A blanket or rug can be spread out for the dog to lie down on during PFR training. The rug gradually acquires a calming effect by way of association with PFR training. The dog can be trained to go to the rug and stay there at times of increased arousal associated with social excesses. Finally, the rug can be used to generalize the effects of relaxation and desensitization from the massage situation to other places. Conditioned comfort rugs can play a useful role in various fear-reduction procedures (Hothersall and Tuber, 1979).

PFR Techniques

1. PFR training progresses through graded postures ranked in terms of relative relinquishment of control and postural potential for inducing relaxation. The stepwise resistance (muscular tensing) and letting go in response to physical prompting and blocking is an intrinsic part of the PFR training process (see *Posture-facilitated Relaxation* in Chapter 6), without which a rapid and deep relaxation response is not achieved.

- PFR training begins with a collar control, reassuring eye contact, and a soft smile (friendly face), followed by a series of physical prompts causing the dog to stand, sit, lie down, and roll over onto its side. In addition to being the most control-relinquishing posture, the recumbent posture is the one most conducive to the

induction of a deep relaxation response (Figure C.1).

- If the dog becomes overly aroused or resistant, the massage is limited to actions and postures that it tolerates best and then additional steps are gradually added as its ability to relax and cooperate improves.
- Transitions triggering resistance can be worked through by repeating the same prompt and control with vocal reassurance ("Relax") and additional massage, until the dog shows signs of increasing acceptance and relaxation.

2. Each posture is physically prompted and maintained with vocal prompting "Relax." Otherwise, talking to the dog is minimized, except as needed to provide occasional reassurance and comfort.

3. The dog is paced through the massage sequence according to its response to each step. With practice, the speed of induction improves, especially with the aid of an olfactory-signature stimulus. Some puppies and dogs appear to be more responsive to a rapid sequencing of postural shifts and faster massage activity, whereas others require slower steps and more sustained massage.

4. The best results are achieved by matching handling and massage activities to the dog's temperament and needs. Some dogs prefer firm handling and massage, whereas others require more sensitive and gentle handling and massage. Oppositional behavior should be managed patiently but firmly, constantly guiding the dog back to the posture and position required. Going back to a previously successful step in the PFR cycle can be helpful, thereby increasing the relaxation response before trying to move ahead again.

- Physical assertions of control and TO, though sometimes necessary and expedient, are always reserved for those situations where affectionate persuasion has failed and where alternative courses of action are judged inappropriate.
- PFR training may challenge the dog and momentarily raise competitive tensions, but it should never be deliberately provocative or adversarial or degrade into manhandling. Competitive tensions are gradually resolved via the counterconditioning effects of increasing relaxation and trust.

5. Each massage stroke should be performed with the intention of intensifying the relaxation response. Absentminded rubbing does not produce the same benefit as focused massage.

6. The rhythm of massage should be slow and steady, with the time spent on each stroke, and the interval between strokes kept approximately the same. As the dog's response to PFR training improves, the massage stroke can be varied as needed to intensify the relaxation effect.

7. PFR training should be performed with a high degree of order, consistency, and precision from session to session. Predictable massage actions, controls, and manipulations gradually promote a dog's feelings of enhanced comfort, safety, and relaxation (security).

8. During the massage, the trainer should focus on breathing and project from the belly to the hands a feeling of comfort and care.

9. After several massages in which a progressively enhanced relaxation response is achieved, an olfactory signature is introduced in the context of thermal touch and the induction of a deep relaxation response. Gradually, the olfactory signature is presented at progressively earlier points in the PFR sequence. Eventually, the scent is presented just before the PFR cycle is initiated, thereby forming a conditioned association with the initiation and induction of relaxation. When fully conditioned, the odor should help to facilitate the PFR-training process, as well as improve the dog's responsiveness to various behavior-therapy procedures. The conditioned odor appears to enhance the dog's receptivity to counterconditioning efforts by directly helping to restrain aversive arousal or by altering the dog's appraisal of stimulation occurring in the presence of the odor.

10. A record of the dog's response to various prompts and controls should be kept to track its progress. In addition to general impressions regarding the dog's relative resistance or compliance at various stages of the PFR cycle, ranked on a point scale from 1 (resists: struggles constantly) to 5 (compliant: fully cooperative), heart rate should be recorded. A resting heart rate should be measured before PFR training is initiated, recorded after the dog is prompted to stand, and meas-

ured immediately after the petting period at the conclusion of the PFR cycle, either by counting beats with fingers pressed over the femoral artery for 15 seconds or by using an inexpensive radiotelemetry device (see *Devices Used to Monitor Autonomic and Stress-related Changes* in Chapter 9). Changes in heart rate provide an objective measure of change occurring as the result of PFR training over time.

PFR Training Instructions

Collar Control

The collar control is secured by grasping the collar at approximately at 4 and 8 o'clock. While holding the dog's head securely, the jaw muscles are rhythmically massaged with the thumbs moving in a circular direction, while the trainer maintains affectionate eye contact, saying "Relax" in a reassuring tone.

Stand Prompt and Control

Next, the collar is grasped by the right hand at about 9 o'clock while the left forearm goes under the dog's belly bringing it up and around to the front. The trainer is aligned perpendicularly with the dog forming a T shape—an ethologically significant orientation (Fox, 1971). As the dog is steadied in the

standing position, the left hand moves to the back of the neck where a rhythmic massage is applied to the neck, withers, and shoulders. The pressure of the massage stroke varies according to the dog's response to the stimulation. Some dogs and puppies may find such handling provocative and may attempt to wiggle out of the position, movement that should be prevented by placing the left forearm under the belly and shifting the puppy back into proper alignment.

It is important to maintain the massage for at least 30 seconds. If the dog struggles or attempts to sit, the action is prevented, and the dog is prompted back into the stand position. As the dog settles, its heart rate should be measured at the femoral artery by counting the number of beats that occur during a 15-second period.

Sit Prompt and Control

Once the dog accepts the stand control and massage, the left hand moves slowly and rhythmically down the spine until reaching the hip bone. The massage stroke along the spine is performed with a slow inchworm action. The hand is then opened across the breadth of the hip. With the thumb and first two fingers placed into the slight depression just anterior to the iliac crest, a gentle pincer pressure is applied until the dog sits. As the dog sits, the trainer says "Relax" and extends the massage to include the shoulder and lumbar muscles. When the sit posture is prompted, some dogs and puppies may resist and attempt to escape by shifting out of position or turning and mouthing on the hand. If such struggling does occur, it should be discouraged and the puppy prompted to complete the action, perhaps by pushing forward from behind the stifle. Pushing down on the rump should be avoided. Although assertive control and prompting are sometimes necessary, especially during the first or second cycle of PFR training, it is far better to achieve each postural transition without evoking excessive opposition.

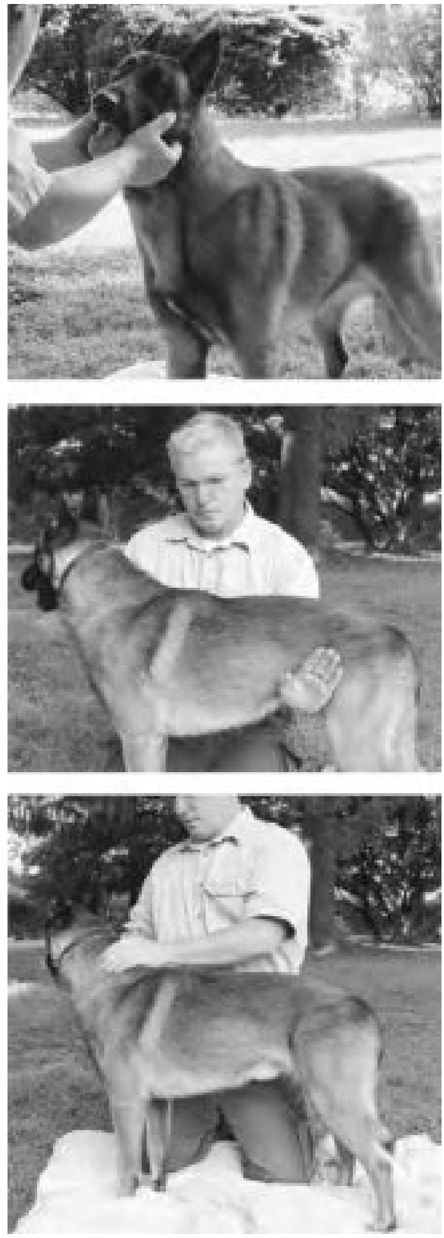

FIG. C.2.a. Stand prompt and control.

Down Prompt and Control

The left hand grasps the collar from behind the neck at a point slightly left to the midline with the left forearm laid along the dog's back. A steady downward pressure is applied as the right leg is grasped at the elbow and pulled forward as the dog is lowered down. When prompted into the down position, the dog's back should lean toward the handler. Once the dog settles into the down position, massage is applied over muscled areas of the shoulders, hips, and upper legs. The fingers of

FIG. C.2.b. Sit prompt and control.

FIG. C.2.c. Down prompt and control.

the massage hand should be closed together and slightly cupped. The best all-purpose massage stroke is achieved by moving the fingers in a circular or spiraling movement over muscled areas. Carefully following and participating in the developing relaxation response help to guide the massage process intuitively. The trainer should focus on breathing in a rhythmic manner and actively feel the relaxing effects of the massage develop. When performed properly, massage benefits both the trainer and the dog.

Again, despite the most gentle and patient handling, some reactive puppies and dogs may respond aggressively to such manual control, perhaps necessitating more secure

restraint (muzzling) or other emergency control measures (e.g., time-out). Limiting postural shifts to the stand and sit may be necessary in the beginning, at least until the dog learns to accept the massage and starts to relax, whereupon the down control can be attempted again.

FIG. C.2.d. Lateral prompt and control.

Lateral Prompt and Control

Once the dog accepts and relaxes in the down position, it is rolled over onto its side. This maneuver is accomplished by placing the left hand on the lumbar muscle just in front of the hip. After pushing the dog's elbow under its body, the right hand is placed (knuckles up) over the neck so that the little finger is situated just behind the base of the jaw, whereupon the dog is rolled over onto its side. As the dog accepts the lateral control, the fingertips of the right hand are placed on the temporal muscle just in front of the ear while the fingertips of the left hand are placed on the masseter. A rhythmic massage is carried out with the fingers moving circularly in opposite directions. In addition to observing the dog's rate of breathing, the commissure of the eyelid should be monitored as an indicator of building relaxation. As the dog relaxes, the frequency of blinking decreases as the eye begins to close and finally shuts.

Ear, Jaw, and Lateral Massage

As the relaxation response deepens, the ear is taken by the thumb and index finger of the right hand and massaged. The thumb is then inserted gently into the ear canal and slowly moved outward to the tip of the ear. Most dogs and puppies appear to enjoy this very much and often exhibit a reflexive sigh as the thumb is moved about in the ear canal. This reflexive response, discovered in the context of PFR training and called the auricular relaxation reflex, usually precedes a deepening of the relaxation response. Next, the lower lip is massaged along the length of the jaw with tight spiraling movements. Attention is then turned to the upper shoulder and various muscles and joints of the foreleg. The front paws are carefully manipulated with each digit receiving focused massage. The massage is gradually moved over the rest of dog's body with focused massage applied to the lumbar area and hip, the hindquarters, the various joints, the tail, and the rear paws. In addition to the circular movement previously described, the heel of the hand is used to produce a simultaneous kneading effect, complementing the more focused movements of the

fingertips. Lateral massage is limited to the left side of the dog's body.

Massage on the left side of the body produces a contralateral effect on the right hemisphere of the brain. The right somatosensory cortex plays a prominent role in social and emotional information processing (Adolphs, 2001). In addition, the right medial prefrontal cortex appears to be asymmetrically involved in the cortical integration of emotional and physiological responses to stressful arousal (Sullivan and Gratton, 1998). Massage-induced alterations of activity in the right cortex may promote positive social responsiveness as well as help to modulate emotional and physiological responses to restraint. Whether unilateral massage exerts a benefit via these cortical mechanisms is unknown, but unilateral massage does appear to perform better than bilateral massage for inducing a rapid and deep relaxation response.

FIG. C.2.e. Ear, jaw, and lateral massage.

Thermal Touch

As the relaxation response progresses and reaches a peak (as evidenced by decreased respiration rate, relaxed muscle tone, and lowered or closed eyelid position), the right index finger and forefingers are drawn together and placed on the temporal muscle mass located just in front of the ear. A gentle continuous pressure is applied for 10 to 15 seconds together with a steady care intention is focused on the dog. As a sensation of warmth develops between the fingertips and the point stimulated on the dog's head, the hand is slowly lifted away and centered approximately 2 to 3 inches above the dog's belly. From there, the hands are moved slowly over the dog's body, circulating a sensation of warmth in a manner resembling a slow movement through water.

Olfactory Signature

The last step in the massage is to link an olfactory stimulus or signature with the relaxation response. Normally, the odor of the owner's hand or other family members is presented as the olfactory signature. Alternatively, a dilute (1:30–50) odor (e.g., sandalwood, lavender, or chamomile) is presented during the thermal-touch procedure and the induction of a deep relaxation response. A scant drop of the dilute odor is rubbed into the hands. Alternatively, 2 or 3 drops of the odor

FIG. C.2.f. Thermal touch.

are put on a tissue that is then folded several times into a small square that can be rubbed between the thumb and index finger to draw out the odor. Again, the hands are moved slowly above the dog's body without actually touching, but close enough for the heat and movement of the hands to be felt by the dog

FIG. C.2.g. Olfactory signature.

as a thermal sensation. As the relaxation response deepens, the right hand is cupped gently around the dog's nose, stimulating a sniffing action and surprise. The surprise is of critical importance for forming a rapid and strong association between the state of deep

FIG. C.2.h. Transition petting and release.

relaxation (the physiological expression of acceptance and trust), the odor, and subsequent petting and release. Another method involves placing a small amount of the selected odor on the lips and blowing the scent slowly and unobtrusively over the dog's head from behind, just as an unscented hand is cupped over the dog's nose. The trainer should not blow sharply or directly into the dog's face and should sit upright and behind the dog when performing the procedure. Alternatively, a gentle smooch sound follows the scented breath and is timed to occur just as the unscented hand is placed in front of the dog's nose. The scented-breath technique is based on subtle associative linkages formed between the conditioned odor, surprise, and relaxation. Finally, in some olfactory-conditioning procedures, the odor is delivered from a squeaker bulb by slowly squeezing it and then releasing the slightly depressed bulb to produce a soft squeak.

Transitional Petting and Release

The dog is gradually transitioned out of the relaxation response with firm, long-stroke petting actions that consciously and deliberately follow the lay of coat over the head, neck, back, and chest. As the hindquarters are petted, the dog's heart rate should be measured again and recorded. At the conclusion of the petting phase, the trainer quietly says "OK" and gently claps a couple of times. As the dog stands up, the collar control is applied again with affectionate eye contact and vocal reassurance before the puppy or dog is released for play, training, or another cycle of PFR training. Note the more focused eye contact given by the dog in comparison to response exhibited with the collar control initiating the PFR cycle.

Puppy Temperament Testing and Evaluation

Temperament Testing

In Volume 2, much was left to the imagination with regard to the procedures used to perform puppy temperament tests (see *Puppy Temperament Testing and Evaluation* in Volume 2, Chapter 2). In addition to describing in detail how the various tests are performed, the potential significance of the information also remains to be discussed. The tests described below borrow from the basic research performed by Scott and Fuller (1965), the testing procedures used by the Bio Sensor Research Team (U.S. Army Super Dog Program), and testing recommendations suggested by Michael Fox (1972). Although temperament tests are not routinely performed, they can be used as an objective tool for evaluating a variety of social, emotional, cognitive, and motivational dimensions in puppies. For applied dog behaviorists needing a highly objective assessment tool for supplementing behavior questionnaires and other instruments (e.g., the Puppy Behavior Profile), such testing may be useful. Temperament tests may also be useful for research purposes, wherein an objective baseline of information is needed. For most practical training purposes, however, the Puppy Behavior Profile, along with interview information and direct observation, provides sufficient information to determine a puppy's training needs.

The Puppy Temperament Test may be most useful in the case of older puppies about whom little information is known. No test, no matter how comprehensive and detailed, can reveal every facet of a puppy's behavior or potential. In addition to specific tests, real-life observations of a puppy's behavior under various circumstances and stressors can be highly revealing and useful. Although an owner can play the role of handler in many of the tests, the administering trainer, especially in cases where special skills may be necessary to control the puppy properly, should perform the role of handler. The tests are designed for puppies from 10 to 20 weeks of age, but can be easily modified for use with younger and older dogs.

Testing Procedures

A. Social Attraction (Passive Handler)

Both the owner and the trainer can alternately play the role of handler. The scorer (owner) holds the puppy on a 6-foot leash as the handler moves to a spot approximately 20 feet

away. After approximately 10 seconds, the handler calls the puppy's name and claps to get its attention and the scorer releases the puppy. If the puppy hesitates, it is encouraged vocally and the handler might crouch down, as well. As the puppy approaches, the handler should once again stand upright. After a brief moment of standing still, the handler should praise the puppy and toss a treat on the ground and pick up the leash. Further information can be obtained by reversing the roles of handler and scorer. Now, the trainer holds the puppy's leash as the owner walks away. The owner repeats the handler procedure in an identical manner. Differences in the puppy's behavior toward the trainer and the owner are noted.

B. Social Attraction (Active Handler)

Holding the end of a 6-foot leash, the handler steps away while calling the puppy's name. If the puppy hesitates, the handler (owner or trainer) calls the puppy's name again and slaps his or her thigh. If necessary, the leash can be dropped as the handler jogs away from the puppy while at the same time encouraging it to follow along with cajoling words and gestures. If the puppy forges into the leash, the handler should run along to keep up.

C. Contact Tolerance

Most puppies enjoy being petted and handled, but some are intolerant of tactile stimulation and may become agitated or overly aroused by taction. For highly reactive or excitable puppies, petting and handling should be limited to minimally provocative stimulation. In addition to petting the puppy's head, body, and tail, the handler should attempt to examine the puppy's mouth, ear's, and feet.

D. Physical Controls

These various controls are typically performed by the trainer, and the owner is later instructed on how to perform them in the context of posture-facilitated relaxation training. Care should be taken not to agitate the puppy unnecessarily. During the performance of each control, the puppy is massaged and reassured. If the puppy becomes highly reactive and fails to calm in response to massage and vocal reassurance, the score for that control is noted and the physical control portion of the test concluded. At the beginning of the test, resting heart rate should be measured, followed by a second measure taken at the end. For specific instructions on prompting the controls, refer to Appendix C, *Posture-facilitated Relaxation (PFR) Training*.

E. Impulse Control (Possessiveness)

For the safety of children and others in the home, it may be helpful to determine the degree of risk that a puppy poses with respect to possessive aggression.

The trainer, taking care not to provoke the puppy unnecessarily, always performs this test with the puppy restrained on a leash. The beef bone or other desirable object used for this test should be tied to a piece of twine, allowing the trainer means to remove it safely from the puppy if the puppy becomes aggressively aroused. The puppy is left with the bone for 1 minute as the handler stands 10 feet away. As the handler approaches the puppy, the leash is picked up to restrain the puppy, if necessary, and the handler reaches toward the bone, just out of the puppy's reach. If the puppy growls or snaps, the attached twine is used to pull the bone away. In the case of a puppy that accepts close contact and petting while it chews on its prize, the trainer can attempt to take away the bone. If there is any doubt about the puppy's intention, the bone is removed by pulling the piece of twine, without applying a muzzle control. If the puppy releases the bone without objection, it is rewarded with a treat offered as trade and the opportunity to have the bone back again. In the case of threatening puppies or puppies appearing stiff with intense possessive interest, testing for bite propensity should be considered. In such cases, a piece of broomstick 1-foot long is covered on one end with an 8-inch square of cloth neatly wrapped around several layers of batting and secured with rubber bands at the base of the wad. The

cloth and batting should be replaced after every use to minimize the presence of confounding odors. Alternatively, fingers of a glove can be filled with cotton balls and shaped into the form an approaching hand. The probe stick is passed under a jacket sleeve, with the padded end or glove protruding out. As the puppy is approached, the leash is secured and the probe stick is moved toward the bone, mimicking normal caution when doing so. If the puppy ignores the intrusion, it is petted, given a food reward, and left alone to enjoy the bone for an additional minute. If the puppy attacks the probe stick, the bone is snatched away and the puppy timed-out. This test is not designed for adult dogs, wherein more precautions and safeguards may be needed to ensure safety for the trainer and the dog. Although the test is useful for detecting possessive aggression tendencies, failure of the puppy to show such behavior should not be taken to imply that under some set of circumstances it may not exhibit aggression while in possession of some prized item.

F. Impulse Control (Delay of Gratification)

During this test, the handler (owner or trainer) requires that a puppy stand quietly before receiving a treat. If the puppy already knows how to sit, the handler vocally prompts the puppy to sit, but, additionally, requires that it hold the sit position as the treat is moved toward its mouth. The puppy is required to take the treat gently. By standing on the puppy's leash, jumping and lunging are thwarted.

G. Ball Play

A puppy's willingness to chase and retrieve a tennis ball is assessed by first briefly causing the puppy to mouth or tug it. Interest can also be enhanced by bouncing the ball against a wall a couple of times before throwing it. The ball is rolled approximately 15 feet away. If the puppy runs after it and picks it up, it is encouraged vocally and with smooching and clapping to return with it, whereupon the puppy is rewarded with affection and tug before the ball is taken. The puppy is given three opportunities to fetch the ball and scored according to the best performance in terms of drive and cooperation, ideally chasing the ball enthusiastically and bringing it straight back without hesitation. In this test, the least favorable responses are to ignore the ball (deficient drive) or to run away with it (deficient cooperation), with the latter being preferable to the former. If the puppy fails to return or runs away with the ball, the handler should appropriately lure the puppy back or step on the leash or long line and take the ball away from the puppy. The puppy is returned to the original spot and allowed to mouth on the ball for a moment before the ball is thrown again. For smaller puppies, soft toys or smaller balls should be used.

H. Rag Play

A strip of cloth (e.g., burlap) is presented to the puppy and dangled or dragged back and forth for it to grab. If the puppy takes the rag, it is encouraged with praise to tug and hold on. Puppies are prompted to release the rag by offering them a treat. Another variation allows the puppy to keep the rag, and it is evaluated for its subsequent behavior. For example, the puppy runs off and shakes the rag, the puppy runs off and chews the rag, the puppy takes the rag and returns promptly to play more, or the puppy drops the rag. In addition, puppies are evaluated for their level of possessiveness when approached while in possession of the rag.

I. Separation Reaction

During the separation test, the puppy is usually placed into an unfamiliar room for 1 minute. A small room is ideal, but a larger room can also be used, as well. To prevent the puppy from wandering too much during isolation, it can be placed into a holding pen. A highly desirable treat or hollow rubber toy smeared inside with peanut butter is presented to the puppy. In the case of puppies showing a high level of separation reactivity, a piece of clothing with the owner's scent is

left with puppy. A third variation involves evaluating the puppies response to a mirror secured to the back of the door.

J. Reactivity and Problem Solving (Barrier Frustration)

A wire-mesh barrier is set up by stretching out a hinged holding pen, forming a crescent or V shape. Stakes are placed in the ground to support the barrier so that it cannot be knocked down if the puppy runs into it or jumps against it. The puppy is placed in the middle of the convex side of the barrier while the handler (owner) stands about 5 feet away on the opposite side. The scorer holds the puppy by a leash as the handler drops several small treats into a bowl on the ground. The handler should move about 2 feet back from the bowl and call the puppy, as the scorer releases the leash. In addition to scoring the sort of behavior exhibited by the puppy, the length of time that it takes to get around the barrier should be noted. If the puppy fails to solve the problem within 1 minute, the handler goes around the barrier to join the puppy and then demonstrates to the puppy how to get around the barrier. The handler places another small treat in the bowl and steps back from the barrier. If the puppy still fails to get around the barrier, it is taken around by the scorer, whereupon the puppy is received with affection and permitted to eat the food in the bowl. In addition to the specific items on the score sheet, the scorer should note whether the puppy goes to the handler first or the food, improvement occurring as the result of demonstration, and unusual behaviors.

K. Startle Reflex

A relatively strange area is usually selected for this test. Normally, the handler is located about 3 to 5 feet behind the puppy, and a seven-penny shaker can is dropped to the floor from waist high. The distance and size of the shaker can are determined by the puppy's relative sensitivity to auditory startle. Startle tests are typically reserved for puppies over 12 weeks of age. Any modifications of the basic test format should be noted on the test form. Puppies showing extreme reactions can be subsequently given a prepulse-inhibition test. In this case, the can is tapped with the flick of a finger as it is dropped. Any changes in the puppy's startle response are noted. After the startle event, the handler should encourage the puppy to come, receiving it with affection and petting, rewarding it with food, and tossing a ball. In addition to the auditory startle test, the puppy can be exposed to startle stimulation involving a visual component. For example, a spring-loaded umbrella can be opened at a perpendicular angle to the puppy from 6 to 8 feet away. Another variation involves dragging some novel rattling object (e.g., a toy wagon) near the puppy. Whenever possible bilateral tympanic temperature and heart rate measurements should be taken before and after exposure to novel and startling stimuli.

The following social cognition tests have been added to the original evaluation format:

L. Cognition (Expectancy)

The puppy is given 20 small treats from the right hand in the context of attention training (squeak, head turn, click). After a brief period, the handler presents a small biscuit held between the fingers of the left and right hands at approximately 12 to 16 inches from the puppy's nose. The hands are slowly separated so that the biscuit remains in the puppy's view, but is kept in the left hand. Since the puppy has learned to find the food treat in the right hand, it will tend to show a persistent tendency to follow the right hand, despite the presence of sensory information indicating an opposite fact (i.e., the treat is in the left hand) (see *Practical Example* in Volume 1, Chapter 7). The results (1 to 5) are measured by counting the number of trials the puppy requires to learn not to follow the right hand on two consecutive trials.

M. Cognition (Delayed Response)

The puppy is kept on leash at a doorway while the handler shows it a treat and places the treat in a small bowl situated behind one of three shoe boxes standing on their sides, thereby concealing the item from view. The

boxes are placed 5 to 7 feet apart. The middle box never contains food. The puppy is given several practice trials allowing it to run to the box where the food is hidden after waiting 1, 3, 5, 10, 15 seconds. The practice is continued until the puppy is able to able to find the food without error. Next, after the food treat is concealed while the puppy looks on, the door is closed and opened again after an increasing period (1, 3, 5, 10, 15 seconds), whereupon the puppy is released to locate the food item. The puppy is given five progressively longer trials, provided that it goes to correct box each time; otherwise, it is required to repeat the step until it succeeds. The results are evaluated in terms of the longest delay in which the puppy performed correct choices after five trials (see *Learning and Trainability* in Volume 1, Chapter 2).

N. Social Cognition (Passive Direction)

The arrangement is the same as just described, except the food item is concealed after the door is closed. The handler remains standing behind the shoe box where the food item is hidden. The puppy is released after 10 seconds from behind the door. The results are evaluated in terms of the number of correct choices in five trials.

O. Social Cognition (Active Direction)

An identical arrangement as the foregoing is set up, except the handler stands or sits on a chair behind the middle box. The puppy is given 10 trials of increasing difficulty (ranked 1 to 5) with respect to handler directional cuing: the handler makes a tapping action toward the correct box, the handler reaches and points at the correct box, the handler orients and points toward the correct box, the handler repeatedly turns and glances toward the box, or the handler steadily stares at the correct box. The puppy is given 10 trials during which it is allowed to advance to the next step after a minimum of two successful choices. After two consecutive incorrect choices, the puppy is returned to a previously successful step. The results are evaluated in terms of the number errors and the ranked difficulty of directional cuing.

In addition to the specific tests just outlined, impressions are recorded about the puppy's response to familiar and unfamiliar situations and objects. General impressions of fearfulness, activity levels, and excitability should be recorded (e.g., high, moderate, or low). Any behavior observed during testing that may help clarify the direction and significance of the test results should be noted and given appropriate consideration. In some cases, it can be useful to repeat tests on a weekly basis to observe changes resulting from maturation or training.

Significance and Interpretation

Several temperament tests have been devised and recommended to help place puppies in homes consistent with their behavioral needs (see *Temperament Testing* in Volume 1, Chapter 5). However, in recent years, the predictive value of such tests has fallen under significant doubt and controversy (see *Temperament Tests and Aggression* in Volume 2, Chapter 8). Although the results of such tests [e.g., restraining a puppy on its back, petting it along its topline, and lifting it off the ground (Campbell, 1972)] may be useful as general reactivity *indicators* (see Clark, 1994), they do not appear to be very useful as *predictors* or means for detecting stable *dominance* traits or propensity for dominance-related aggression (Beaudet, 1993).

The detection of stable traits and characteristics or interpreting the test scores as predictive indicators of adult behavior is not the primary purpose of the tests just described. The primary purpose of testing is to help define specific behavioral propensities and tendencies needful of training and therapy. Testing provides an objective picture of a puppy's behavioral potential (excesses and deficits) at the time of testing. In addition to identifying weaknesses needing attention, testing can also help to identify strengths to nurture and actualize further. Behavioral tendencies that persist despite dedicated training efforts and the influence of development may presage adult propensities.

Excesses associated with tests A and B are often misinterpreted as indicators of social dominance, appearing to confound opposi-

tional behavior with playful competitiveness. Unfortunately, the mischaracterization of social exuberance as an oppositional threat is not just an innocuous error, but an evaluation that has resulted in significant misunderstanding and maltreatment of puppies in training. A host of manhandling techniques has been developed to "break" such puppies to make them more submissive—a sad situation because most of these puppies are already submissive and in search of leadership; that is, their behavior is actively submissive—not dominant. Although exceptions certainly exist, most often puppies that use threats and overt aggression toward people do so as the result of mishandling and a failure to establish more competent and cooperative means to negotiate interactive conflicts and tensions. Although puppies affected by oppositional problems may also exhibit intrusive excesses, for the most part low scores on these tests are indicative of excitability, social enthusiasm, confidence, and playful competitiveness; such puppies may be characterized as social extraverts. In the context of Pavlov's typology (see *Experimental Neurosis* in Volume 1, Chapter 9), such extraverted puppies correspond to the sanguine or s type: friendly, socially responsive, focused, energetic, and highly sensitive to the effects of reward and less responsive to the effects of punishment. Puppies with low scores (1 and 2) are socially (and usually physically) healthy and outgoing (stable extravert), but needful of social limits and compliance training. In addition, play training may be very beneficial as a means to redirect their competitive enthusiasm into more constructive and cooperative outlets. At the other extreme, puppies exhibiting high scores (4 and 5) may be affected by significant social tendencies associated with introversion. Such puppies may show a generalized lack of behavioral output (inhibited) and may be socially reserved, passive, adverse to play, and highly sensitive to the effects of punishment and less responsive to the effects of reward (Gray, 1991). Puppies scoring 3s on tests A and B show a healthy balance between extraverted and introverted influences and, depending on future developmental, socialization, and training influences, may progressively move in the direction of increased introversion or extraversion (Figure D.1).

Under the influence of adverse developmental influences, extraverted puppies may become progressively unstable in the direction of Pavlov's choleric type (c type), being prone to show contact aversion (touch sensitivity and irritability), impulsive behavior, frustration and restraint intolerance, and nervous excitability. The c type is prone to panic-evoked aggression (rage) via the simultaneous and escalating arousal of fear and anger emotional systems. Unstable extraverts require highly structured reward-based training activities aimed at reducing interactive conflict and tension, together with management precautions designed to minimize provocative stimulation. The goal of training and management efforts is to reduce behavioral stress while increasing the dog's ability to gain a better state of security (comfort and safety) and trust. The c type tends to react to punishment rather than adjust to it, making physical punishment highly problematic in the case of such dogs. Mismanaged introverted puppies, on the other hand, may become progressively unstable and prone to develop melancholic tendencies (anxiety and depression) and behavior problems, e.g., social aversions, fears and phobias, and compulsive disorders. Whereas the c type tends to be affected by excessive excitability and impulsiveness (hyperactivity and stimulation seeking), the melancholic type(m type) tends to respond to the environment in a highly fearful, inhibited, or helpless manner. Under the influence of stability-enhancing training activities, introverted puppies can learn to cope more effectively with the environment and become progressively more confident and relaxed. In contrast, phlegmatic types (p types or stable introverts) tend to be passive, controlled, calm, and balanced with respect to their social and environmental interaction. Whereas s-type puppies may have trouble learning to wait and to delay gratification, such abilities come more naturally to p-type puppies. According to Pavlov (1994), all dogs can be grouped according to these four basic temperament types:

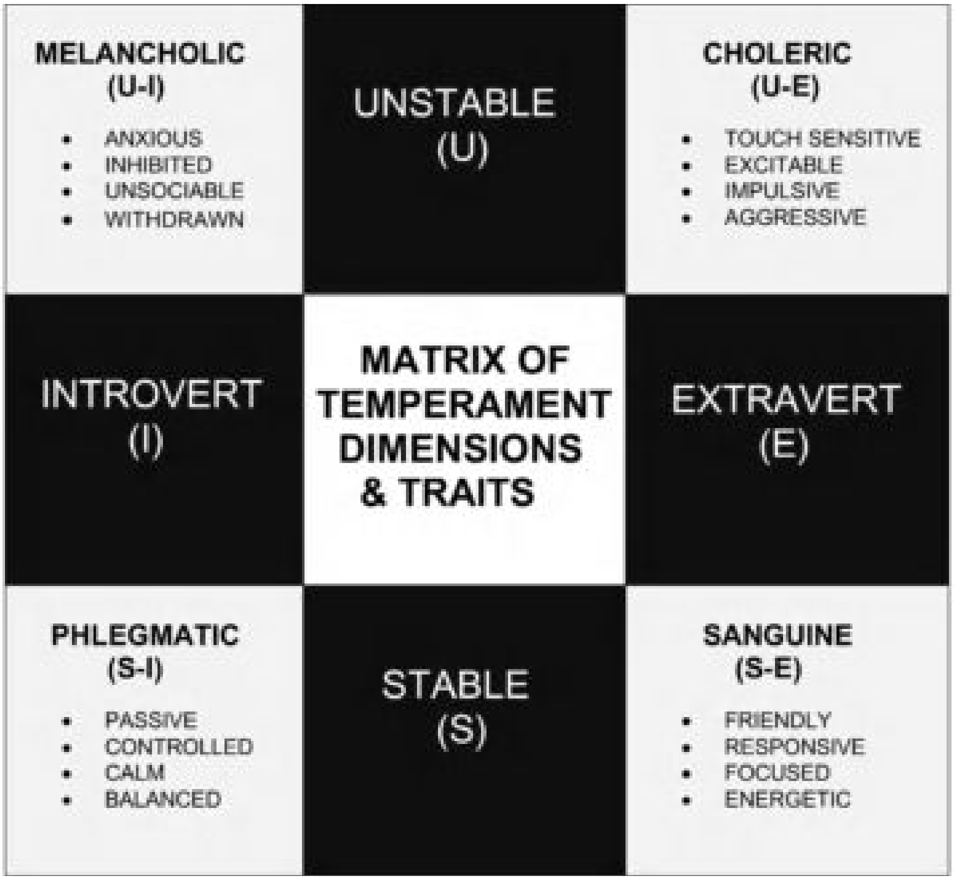

FIG. D.1. Matrix of temperament dimensions and traits. After Pavlov and Eysenck (see *Experimental Neurosis* in Volume 1, Chapter 9).

> Thus all our animals are divided into four definite groups: two extreme groups of excitable and inhibitable animals [choleric and melancholic] and two central groups of balanced but different animals: some very quiet [phlegmatic] and others extraordinarily lively [sanguine]. We have to consider this a precise fact. (216)

Whereas tests A and B give some indication of a puppy's social development in terms of relative extraversion or introversion, subsequent tests may serve to detect specific stabilizing or destabilizing influences. For example, high scores (1 and 2) on test C may indicate heightened touch sensitivity and excitability consistent with Pavlov's c type, whereas low scores (4 and 5) may indicate some degree of insecurity or social aversion, indicators consistent with Pavlov's m type. Puppies scoring 3 exhibit a fairly balanced response to contact, consistent with p type (stable introvert). Stable extraverts (s types) also show strong playful responses (mouth, paw, and jump up) while being handled. The cause of their behavior is the result of playful enthusiasm and poorly defined social limits—not contact aversion or impulse dysregulation. Differentiating biting and other excesses due to contact aversion versus playful enthusiasm is facilitated by the control tests (D1–D5). During control tests, unstable extraverts (c types) may become progressively aroused and resistant despite vocal reassurance and massage. Stable extraverts (sanguine), on the other hand, are typically more receptive to the calming effects of reassurance and massage. C types may become reactive and aggressive when rolled

on their side, whereas s types are more likely to accept such restraint without much resistance or struggle and rapidly calm down. S types are highly responsive to relaxation training, often falling rapidly into a deep relaxation response as massage proceeds. M types may struggle to get away or appear to resent physical restraint. P types typically show high scores (4 and 5) by passively accepting control and appearing to enjoy massage, but often enter into the relaxation response more slowly than s types.

Test E helps to differentiate these various temperament types further as well as providing an indicator of behavioral thresholds controlling aggression in response to appetitive loss or frustration (see *Anxiety, Frustration, and Aggression* in Volume 2, Chapter 8). Puppies getting low scores (1 and 2) in tests C and D1–5 that also show intense growling or snapping when approached while possessing a prized item may be at significant risk for serious problems unless significant and sustained behavioral efforts are undertaken. Well-socialized s and p types typically score 3 and 4 in the possessiveness test. M types may ignore the bone as the result of high levels of anxiety competing with appetitive arousal, a significant test for confirming such tendencies when other test scores appear to point in the direction instability (e.g., anxious, inhibited, unsociable, and withdrawn). Test F may have some value in detecting impulsive tendencies associated with hyperactivity, especially in the case of older puppies. Repeated jumping up and grabbing for the treat despite blocking (1), may reflect an inability to cope adaptively with frustration, a c-type trait. Stable extraverts (s type) tend to show high levels of excitement and enthusiasm but rapidly abandon impulsive efforts (2) to grab the treat and defer to physical restraint, whereas stable introverts (p type) show a more control and even appetitive response, together with a greater willingness to wait or sit when given a treat. In contrast, unstable introverts (m type) may refuse or avoid taking food.

Tests G and H can be particularly revealing. Puppies that show a natural aptitude for chasing and retrieving things are typically s types that are highly responsive to training for work and competition (see *Learning and Trainability* in Volume 1, Chapter 2). These tests can be further revealing by performing them under both familiar and unfamiliar circumstances. Choleric puppies may refuse to release the rag or stand guard over it with threats and snapping. P-type puppies may show a willingness to retrieve and tug, but typically lack real enthusiasm and sustained interest in the activity. M-type puppies may ignore the ball or halfheartedly chase it, but not pick it up or walk away after giving a brief chase. Unstable introverts (m type) may refuse to take a rag to play tug.

The separation-reaction test (I) helps to segregate excesses and deficits associated with attachment. Most puppies experience some degree of distress when separated in a strange situation. C-type puppies may exhibit sustained distress resulting from exaggerated reactions to loss and frustration. Such dogs may bark in a persistent and demanding way and scratch aggressively at doors. S-type puppies may also rebel at separation, but can be comforted with food or toys (e.g., peanut butter on the inside of a hollow rubber toy). While initially highly aroused, sanguine puppies may bark, but rapidly habituate to distress at separation and engage in diversionary activities. M-type puppies may be highly distressed at separation, reacting under the coactive influence of fear and anxiety, whereas p-type puppies may show a more restrained distress response when isolated for brief periods, but may become progressively distressed by longer separations. Whereas s types tend to bark more than whine, p types are more prone to whine than bark. Whereas s-type puppies appear to be responsive to the calming effects of food, p-type puppies appear to be more responsive to the presence of clothing and other items scented with the owner's odor.

The barrier test (J) is used to help evaluate a puppy's ability to cope with adverse emotional arousal (frustration) while solving a simple problem. Puppies that exhibit intense emotional reactivity and fail to solve the test within the allotted 1-minute period may be subject to significant stress. Again, the c type will tend to obtain low scores (1 and 2), whereas s and p types (exhibiting excitatory and inhibitory balance) will tend to obtain

higher scores. M-type puppies may stay close to the scorer and not attempt to solve the problem. The barrier test may help to identify learning and impulse-control problems. By measuring the length of time it takes the puppy to get around the barrier, the degree of interference can be given an objective measure. The benefits of behavior-therapy efforts may be estimated by comparing barrier test scores over time. Additional information may be obtained in the case of puppies that initially struggle or fail, but learn how to get around the barrier more quickly by observing the handler demonstrating how to do it. Such responsiveness may point to enhanced social learning abilities and sensitivity to human sources of information used to solve problems (Pongrácz et al., 2001).

The way a puppy responds to startling events may strongly affect its ability to learn and perform under aversive situations. Whereas choleric puppies appear to be adversely influenced by frustration, melancholic puppies are typically more vulnerable to startling sounds or movements. During the auditory startle test, c-type puppies may bark at the handler or even run at and grab the shaker can. P-type puppies typically show some evidence of startle, but quickly recover without evidence of lingering fearful arousal. S-type puppies may show significant startle (3) and recover, although some sound-movement-sensitive types may exhibit significant fear with retreat from the situation. Such otherwise stable puppies should receive intensified desensitization and habituation efforts to elevate the relevant threshold. As one might predict, unstable introverts may be significantly affected by the startle test, typically receiving high scores (4 and 5). In addition, to behavioral measures of emotional reactivity, heart rates should be taken before and after startling stimulation. Poststimulation heart rates should be taken 10 to 15 seconds after the event and again after 1 minute. Active and fearless puppies exhibiting low standing heart rates may be prone to develop offensive aggression problems (see *Autonomic Arousal, Heart Rate, Aggression* in Chapter 6), especially if they exhibit threatening behavior during contact-tolerance tests, physical control tests, or impulse-control (possessiveness) tests (see *Behavioral Thresholds and Aggression* in Volume 2, Chapter 8).

A prepulse-inhibition test may be useful in the case of puppies showing unusual responses to startle or other indicators of disorganizing reactivity. Normally, the presence of a comparatively weak stimulus presented just in advance of a startling acoustical stimulus serves to restrain the magnitude of the startle response. The absence of prepulse inhibition is a marker occurring in association with a variety of psychiatric disorders (Braff et al., 2001). Prepulse inhibition is conceptualized as performing a protective emotional function, on the one hand, and a cognitive processing function, on the other. With the occurrence of a startling (dangerous) event, it behooves the animal to stop what it is doing, collect as much relevant information as possible, and rapidly evaluate its significance. Without mechanisms such as prepulse inhibition, the animal may be emotionally overwhelmed by startling events and react blindly to them, perhaps endangering itself in the process. A lack of prepulse inhibition may reflect a gating deficiency affecting sensorimotor processing. Although published data are lacking in dogs, preliminary observations indicate that dogs generally exhibit a strong prepulse-inhibition effect. Future studies designed to evaluate prepulse inhibition in dogs exhibiting serious behavior problems may prove valuable in terms of understanding and treating certain severe canine behavioral disorders. In addition to providing an operational measure of cognitive function, such indicators may offer a neurological marker for confirming behavioral diagnostics and to evaluate treatment efficacy.

Delayed response testing provides another measure of cognitive function (Fox and Spencer, 1967). Delayed response and object permanence abilities operate under developmental constraints, with the dog's abilities appearing to improve with the maturation (Gagnon and Dore, 1994). Delayed response capacities depend on a complex coordination of emotional and cognitive functions that may be disrupted by stress and other disturbances affecting the frontal cortex and working memory (see *Cerebral Cortex* in Volume 1, Chapter 3). Deficiencies in delayed response capacity

may help to more accurately characterize impulse-control problems, perhaps providing a baseline from which to objectively evaluate the benefits of training and behavior therapy. Another useful indicator of cognitive function is the puppy's ability to adjust expectancies in accordance with prediction discrepancies. Adjusting behavioral output to fit sensory input and outcomes associated with instrumental activity is an important aspect of adaptive learning. When events and outcomes occur on a regular basis, the formation of prediction and control expectancies may exert a dominant influence over choices, even in the face of contrary sensory information. On the other hand, a predominance of irregular events and outcomes lacking reliability and orderliness (or lacking the ability to detect and organize such reliability and order) may cause the dog to depend more on direct sensory information to make decisions, with heightened behavioral stress (anxiety and frustration), hypervigilance, and scanning. Test L evaluates a puppy's ability to form a simple predictive-control expectancy and the rapidity with which the expectancy is changed in response to contrary sensory information and the discontinuation of the expected outcome.

Dogs showing compulsive tendencies and therapy-resistant reactive adjustments in association with social anxiety and ambivalent behavior appear to show a strong tendency to perseverate on the right hand after learning to expect food from there. The unproductive choice may continue on for many trials, despite the presence of obvious sensory information to the contrary and growing signs of distress on the dog's part. Such behavior gives support to the notion that habit formation takes place at choice points with the choice itself signifying that the action has undergone reinforcement. It is only through the inhibitory action of attention and impulse control that intelligent hesitation enables the dog to process choice points proactively and to choose well. Thus, the perseveration revealed by this cognitive test may provide information useful for assessing the fitness of executive functions. In addition, the test may reveal the presence of interfering social anxiety and reactive arousal impairing the dog's ability to adjust its behavior to the change. Dogs affected by this perseverant pattern may rapidly shift into a proactive selection mode when the test is performed by a family member or trusted person but may rapidly revert back to the previous pattern if startled or otherwise made uneasy.

The dog's ability to adapt to life with people is in large part mediated by social cognitive abilities. Normal puppies show an innate responsiveness to human directional cuing, especially pointing actions combined with gazing. The capacity of puppies to follow human pointing and gazing to find food and other attractive objects does not appear to depend on learning or developmental age, at least with respect to puppies 9 weeks of age or older (Hare et al., 2002). Interestingly, according to Hare and colleagues, the dog's ability to follow human pointing and gazing cues is superior to the abilities of the chimpanzee and the wolf to follow similar directional cues. The dog's ability to follow directional cues may be the result of linked social, emotional, and cognitive changes produced by domestication. According to Hare, the dog appears to have undergone a "process of phylogenetic enculturation" (1636) by which human and canine cognitive abilities have converged to make social bonding and cooperation possible. Tests M, N, and O provide useful information for assessing cognitive functions that may offer additional insight into the significance of other tests.

Deficits affecting a dog's ability to follow human directional cues or establish eye contact and sustained face gazing may reflect the presence of significant social anxiety and ambivalence, perhaps stemming from a persistent partial retraction of the social engagement system. In order to acquire social information of sufficient quality to promote autonomic attunement, the dog must orient and actively attend to the face in a relatively neutral and trusting way. Some dogs appear to show from an early age a tendency to treat eye contact and neutral facial expressions as threats. Some puppies may act on this negative bias by biting or snapping at the face instead of licking affectionately, which is the normal custom of most puppies. Even those puppies that are strongly motivated to compete and mouth on the hands will usually

shift from biting to kissing when permitted to get close to the face. Even dogs expressing high-reactive thresholds may show such problems at an early causing them to gradually lose their capacity to connect in a rewarding way with people. Although such dogs are usually not at risk of developing aggression problems, they may become increasingly insular and hyperactive or withdrawn. Puppies showing any of these signs should receive intensive therapy aimed at promoting friendly eye contact and social gazing. Target-arc training and play therapy appears to be particularly useful in such cases as a means for invigorating the social engagement system (see *Attention and Play Therapy* in Chapter 8).

Temperament test scores may reveal significant information about how a puppy is emotionally and cognitively organized and prepared to respond to social and environmental stimulation. Four temperament types have been described and characterized in terms of functional behavioral and motivational systems (see *Emotional Command Systems and Drive Theory* in Chapter 6). These types are differentiated by the way they respond to various provocative situations and stimuli. Balanced responses are characteristic of stable extraverts (s type) and stable introverts (p type), whereas unbalanced responses are typical of unstable extraverts (c type) and unstable introverts (m type). While s and p types appear to function under the complementary and balancing influences of the behavioral approach system (BAS) and the behavioral inhibition system (BIS), the instability associated with c and m types appears to stem from heightened BIS sensitivity to signals of punishment (threat and loss) and a reactive affinity with the fight/flight system (FFS) (see *Prediction and Control Expectancies* in Chapter 1). The FFS mediates the expression of escape and attack in response to aversive stimulation and frustration (nonreward).

The BAS and BIS work in relative harmony to mediate adaptation, with the former doing the steering and the latter doing the braking. The FFS is an emergency system associated with the reactive expression of unconditioned fear and anger. S- and p-type puppies and dogs are differentiated by the amount of influence exerted by the BAS and BIS. S types show an increased sensitivity to novelty and reward signals and operate under the dominant activating influence of the BAS (prone to approach), whereas p types are more sensitive to startle and reward signals associated with the avoidance of punishment and operate under the dominant inhibitory influence of the BIS (prone to hesitate). S and p types respond adaptively to signals of reward and loss of reward in the process of organizing behavior. S-type dogs tend to engage in modal strategies (searching, exploring, and competing) aimed at producing positive prediction error (surprise), whereas p-types tend to engage in modal strategies (e.g., hesitating, waiting, and deferring) aimed at avoiding negative prediction error (disappointment). In contrast, c and m types show a reactive sensitivity toward novelty and signals of punishment (risk and loss), predisposing them to reactive appetitive and emotional behavior resulting in opposite adaptations tending toward mania and exploitation, on the one hand, and anxious dysthymia and withdrawal, on the other. Further, whereas extreme c-types expressing low-aggression thresholds (trait aggression) are prone to respond in an invigorated fashion to signals of risk and loss under the influence frustration and anger (attack mode), m-types are prone to respond to risk and loss under the conflictive influence of anxiety or the invigoration of fear (escape mode), and may attack under the catastrophic influence of anger and fear (panic mode) if efforts to escape are blocked. Extreme c- and m-types appear to operate in close affinity with the FFS, recommending strongly against the use of punitive techniques in the control and management of puppies and dogs exhibiting such trait aggression or fear. C and m types require highly structured home environments and consistent reward-based training in order to stabilize them in the direction of the s and p type.

Temperament testing can be used most constructively in the context of assessing and guiding training and socialization activities. However, the results of such testing can easily produce significant potential harm when they are improperly generalized or used to forecast adult behavior. Although conventional temperament tests cannot reliably predict adult

propensities, they may inadvertently influence the eventual development of such problems via social placebo and self-fulfilling prophecy effects (see *Social Placebo* in Volume 2, Chapter 10). With the recognition that temperament tests have limited predictive value, except in the most extreme and obvious cases, breeders and trainers using such instruments should take great care not to overly alarm or plant the seeds of doubt and worry when interpreting and discussing the results of puppy temperament testing. Telling a prospective owner that his or her puppy is dominant or aggressive may adversely influence the way the owner treats the puppy, perhaps setting into motion a chain of events that gradually shapes a relationship based on misunderstanding, mistrust, and misguided training activities—all stemming from the influence of a careless opinion. Instead of being used to prognosticate and label the puppy or dwell on its negative potential, the results should be used to help the owner understand the puppy's behavior and to guide socialization and training efforts toward the actualization of the puppy's positive potential.
